HANDBOOK OF SOIL SCIENCES

PROPERTIES AND PROCESSES

SECOND EDITION

Edited by

Pan Ming Huang
Yuncong Li
Malcolm E. Sumner

To

Pan Ming Huang (*1934–2009*)

Editor in Chief

Dr. Pan Ming Huang died on September 13, 2009, after a short illness. He was a towering leader in the field of soil science, and soil chemistry in particular, having served the profession for over 44 years formerly as professor of soil science at the University of Saskatchewan, Saskatoon, Saskatchewan, Canada. He was a dedicated teacher and author of over 300 journal articles published in the most prestigious journals. In the midst of the revision of the *Handbook of Soil Sciences*, having developed and approved the outline, set the standards for the contributions, and solicited the cooperation of all the associate editors, he unexpectedly fell ill. One of his strengths was his ability to involve, organize, and inspire colleagues to cooperate in pursuing scientific endeavors as was evidenced by his initial inputs into this work. Unfortunately, he passed away before being able to see any of the fruits of his labors, the completed manuscripts. Dr. Huang is survived by his wife, Yun Yin, who was gracious in the handover of all the materials required for us to complete the handbook in a timely manner. We dedicate this book to Dr. Huang as a lasting memorial to his many contributions to soil science.

Contents

Part II   Soil Chemistry

Part III   Soil Mineralogy

Part IV   Soil Biology and Biochemistry: Soil Biology in Its Second Golden Age

Part V   Pedology

Preface

Handbook of Soil Sciences is the second edition of a comprehensive reference work on the discipline of soil science as practiced today. The new edition has been completely revised and rewritten to reflect the current state of knowledge. It contains definitive descriptions of each major area in the discipline, including its fundamental principles, appropriate methods to measure each property, many examples of the variations in properties in different soils throughout the world, and guidelines for the interpretation of the data for various applications (agricultural, engineering, and environmental).

This handbook assembles the core of knowledge from all fields encompassed within the discipline of soil science. It is a resource rich in data, which will provide professional soil scientists, agronomists, engineers, ecologists, biologists, naturalists, and students with their point of first entry into a particular aspect of soil science. The contributions serve those professionals seeking factual reference information on a particular aspect. The handbook provides a thorough understanding of soil science principles and practices based on a rigorous, complete, and up-to-date treatment of the subject matter compiled by the leaders in each field. In general, the following critical elements are present in each part: description of concepts and theories, definitions, approaches, methodologies and procedures, data in tabular and figure forms, and extensive references.

The handbook is organized into two books comprising nine parts, covering the six traditional areas of soil science together with a new part dealing with interfacial interactions among the physical, chemical, and biological regimes within the soil, a part on the interdisciplinary aspects, and a final part on databases. The two books are organized as follows:

Handbook of Soil Sciences: Properties and Processes

Part I: Soil Physics
Part II: Soil Chemistry
Part III: Soil Mineralogy
Part IV: Soil Biology and Biochemistry
Part V: Pedology

Handbook of Soil Sciences: Resource Management and Environmental Interactions

Part I: Soil Physical, Chemical, and Biological Interfacial Interactions
Part II: Soil Fertility and Plant Nutrition
Part III: Interdisciplinary Aspects of Soil Science
Part IV: Soil Databases

The subdivision of each part into a series of chapters was made by the associate editors and, in some cases, may appear to be somewhat arbitrary. The chapters have been arranged in such a way as to produce a thread running through each part. A complete table of contents, which is provided at the beginning of each book, gives a general outline of the scope of the covered subject material. In addition, a comprehensive subject index and an assemblage of units in common usage in soil science are provided at the end.

When the revision of this work was started, Dr. Pan Ming Huang, who was the associate editor for the soil chemistry part in the first edition, took on the role of editor in chief. Tragically and unexpectedly, he passed away in September 2009 in the midst of overseeing this expansive work. At short notice, the publisher approached us to complete this massive task to which we agreed in November 2009. Posthumously, we wish to recognize the vision, hard work, and dedication of our friend and colleague, Dr. Huang, in developing the revised outline of the book and soliciting the participation of all the associate editors and, in turn, the authors.

The chapters of this handbook have been written by many authors, all experts in their own fields, and peer-reviewed by independent reviewers. The nine parts have been carefully edited and integrated by the associate editors, all distinguished soil scientists in their own fields. This handbook is a tribute to the dedication of the authors, associate editors, and the publisher and its editorial associates. We wish to thank all the authors for their valuable contributions, the many nameless reviewers for their useful and helpful comments and criticisms, and the associate editors for all their hard work that they willingly contributed.

We also wish to recognize John Sulzycki who was highly effective in twisting our arms to pick up the threads and continue with the project after Dr. Huang's death, Randy Brehm who continued with the management of this project, and Jill Jurgensen, Vinithan Sethumadhavan, and Suganthi Thirunavukarasu who dealt with the minutiae of the editorial process. In addition, several research associates, graduate and undergraduate students, and visiting scientists, especially Helena Ren, Gaelan Jones, and David Li at the Tropical Research and Education Center, University of Florida, helped us in the editorial process for which we are duly grateful. Finally, we would like to thank our wives, Priscilla and Zhitong, for their patience, sacrifice, understanding, support, and encouragement without which this project would not have been possible.

Editors

Dr. Pan Ming Huang (deceased) was the professor emeritus of soil science at the University of Saskatchewan, Saskatoon, Saskatchewan, Canada, and served for 44 years in that institution. He received his BSc (1957) from the National Chung Hsing University, Taiwan; his MSc (1962) from the University of Manitoba; and his PhD (1966) from the University of Wisconsin, Madison, Wisconsin. His research work significantly advanced the frontiers of knowledge on the formation, chemistry, nature, and surface reactivity of mineral colloids, organic matter, and organomineral complexes in soils and sediments and their role in the dynamics, transformations, and fate of nutrients, toxic metals, and xenobiotics in terrestrial and aquatic environments. His research findings, embodied in well over 300 refereed scientific publications, are fundamental to the development of sound strategies for managing land and water resources in the Earth's critical zone. In addition to developing and teaching courses in soil physical chemistry and mineralogy, soil analytical chemistry, and ecological toxicology, he trained and inspired MSc and PhD students and postdoctoral fellows, and received visiting scientists from all over the world. He served on numerous national and international scientific and academic committees. He also served as a member of editorial boards, including the *Soil Science Society of America Journal*. He served the International Union of Pure and Applied Chemistry and the International Union of Soil Sciences in a number of capacities. He received the Distinguished Researcher Award from the University of Saskatchewan, the Soil Science Research Award from the Soil Science Society of America, the Distinguished Alumnus Award and the Chair Professorship Award from the National Chung Hsing University, and the Y. Q. Tang Chair Professorship Award from Zhejiang University. He was a fellow of the Canadian Society of Soil Science, the Soil Science Society of America, the American Society of Agronomy, the American Association for the Advancement of Science, and the World Innovation Foundation.

Dr. Yuncong Li is the University of Florida Research Foundation (UFRF) professor of soil science in the Department of Soil and Water Science at the Tropical Research and Education Center, Institute of Food and Agricultural Sciences (IFAS), University of Florida in Homestead, Florida. He received his BS (1982) in soil science and agricultural chemistry from the Shandong Agricultural University, China; his MS (1990) in agronomy from the University of Georgia; and his PhD (1993) in environmental science from the University of Maryland. He is also an affiliated professor at the University of Florida's Center for Tropical Agriculture, Hydrologic Sciences Academic Cluster, School of Natural Resources and Environment, and Water Institute, and a courtesy professor at the Shandong Agricultural University. He has received many awards and distinctions including a fellow of both the American Society of Agronomy and the Soil Science Society of America, Food and Agriculture Organization (FAO) Fellow, Wilson Popenoe Award (InterAmerican Society for Tropical Horticulture), Outstanding Paper Award (Florida State Horticultural Society), Jim App Award (University of Florida), Junior Faculty Research Award (Sigma Xi, the international honor society of science and engineering), Senior Faculty Award (Gamma Sigma Delta, the honor society of agriculture), Research Innovation Award (University of Florida), Wachovia Extension Professional Award (Extension Association of Florida), and Research Foundation Professor Award (University of Florida). His research and extension program focuses on water and soil quality monitoring, assessment and remediation, management practices to improve nutrient use efficiency, and nutrient cycling in soils/sediments. He has authored or coauthored over 160 research papers, 70 extension articles, and 15 book chapters. He recently edited a book, *Water Quality Concepts, Sampling, and Analyses* (Taylor & Francis). He serves as an associate editor for *Critical Reviews in Environmental Science and Technology* and *Communications in Soil Science and Plant Analysis*. Additionally, he has chaired or cochaired 20 graduate students, served as a committee member for 24 other graduate students, and supervised 15 postdoctoral fellows and many international visiting scientists.

Dr. Malcolm E. Sumner is the Regents' professor emeritus of environmental soil science in the Department of Crop and Soil Sciences at the University of Georgia, Athens, Georgia. He received his BSc Agriculture (1954) in chemistry and soil science and his MSc Agriculture (cum laude) (1957) in soil physics from the University of Natal, South Africa, and his DPhil (1961) in soil chemistry from the University of Oxford, Oxford, United Kingdom. His alma mater, the University of Natal, awarded him an honorary doctor of science degree in recognition of his career

contributions to soil science. Before coming to the University of Georgia, he was professor and head of the Department of Soil Science and Agrometeorology at the University of Natal, South Africa. He has spent sabbatical leaves at the Agricultural University (Wageningen, the Netherlands), University of Missouri (Columbia), University of Wisconsin (Madison), University of Newcastle-upon-Tyne (United Kingdom), Vista University (South Africa), University of Adelaide (Australia), and the Commonwealth Scientific and Industrial Research Organization (CSIRO) (Australia). Over 90 graduate students and postdoctoral associates have studied under his guidance in South Africa and the United States where he taught courses in soil chemistry, soil physics, and soil fertility. In addition to being a fellow of both the American Society of Agronomy and the Soil Science Society of America, he holds the Agronomic Research Award and the Werner L. Nelson Award for Diagnosis of Yield Limiting Factors from the American Society of Agronomy and the Soil Science Research Award, International Soil Science Award, and the Soil Science Distinguished Service Award from the Soil Science Society of America. He is the holder of many other awards and distinctions including the Sir Frederick McMasters

Visiting Fellowship (Australia) and the D. W. Brooks Faculty Awards for Excellence in Research and International Agriculture (University of Georgia). He has presented addresses at more than 100 universities and research institutions throughout the world on his research findings. He has also served as associate editor for the *Soil Science Society of America Journal* and is a member of editorial boards of many other journals. His published works cover a wide range of topics, including subsoil acidity, the agricultural uses of gypsum, diagnosis of yield-limiting factors, beneficial use of anthropogenic wastes, and transport of nutrients in soils. A widely respected author, Dr. Sumner's works include *Soil Acidity* (Springer-Verlag, 1991), *Soil Crusting: Chemical and Physical Processes* (Lewis Publishers, 1992), *Suelos de la Agroindustria Cafetalera de Guatemala* (University of Georgia, 1994), *Distribution, Properties and Management of Australian Sodic Soils* (CSIRO Publications, 1995), *Sodic Soils: Distribution, Properties, Management, and Environmental Consequences* (Oxford University Press, 1998), and the *Handbook of Soil Science* (CRC Press, 1999). He has authored or coauthored over 350 scientific papers, including 220 refereed journal articles, and has contributed chapters to over 30 books.

Associate Editors

Dr. Paolo Nannipieri (Soil Biology and Biochemistry) received his BSc and MSc biology degrees from Pisa University and his PhD (soil biochemistry) from the University of Pisa. He is a member of the Soil Science Society of America, the Italian Society of Soil Science, and the Italian Society of Agricultural Chemistry. He is currently professor of agricultural biochemistry and head of the Department of Plant, Soil and Environmental Sciences at University of Firenze, Firenze, Italy. He served as president of the Italian Society of Agricultural Chemistry and is currently serving as the president of the Commission 2.3 Soil Biology of the International Union of Soil Societies (IUSS). He is also the editor in chief of *Biology and Fertility of Soils*. He holds several distinctions for his global contributions to soil science.

Dr. Donald L. Sparks (Soil Chemistry) is the S. Hallock du Pont Chair in soil and environmental chemistry, Francis Alison professor, and director of the Delaware Institute for the Environment at the University of Delaware (UD). Dr. Sparks is internationally recognized for his research in the areas of kinetics of geochemical processes and mechanisms of metal/oxyanion/nutrient reactions at biogeochemical interfaces using in situ spectroscopic and microscopic techniques. He is the author or coauthor of 281 publications and 2 soil chemistry textbooks. He has given plenary and keynote presentations at scientific conferences throughout the world and been a lecturer at 80 universities and institutes and serves on the editorial boards of eight scholarly journals. He has received numerous awards and honors, including fellow of the American Society of Agronomy, the Soil Science Society of America, the American Association for the Advancement of Science, the Geochemical Society, and the European Association of Geochemistry; the M. L. and Chrystie M. Jackson Soil Science Award and the Soil Science Research Award from the Soil Science Society of America; the Environmental Quality Research Award from the American Society of Agronomy; the Francis Alison Award, the UD's highest faculty award; UD's Doctoral Student Advising and Mentoring Award; Distinguished Alumni Awards from the University of Kentucky and Virginia Tech; Honorary Membership in the Polish Soil Science Society; and the Geoffrey Marshall Mentoring Award. Dr. Sparks has also served as president of the Soil Science Society of America and the International Union of Soil Sciences.

Dr. Joseph W. Stucki (Soil Mineralogy) is professor of environmental soil physical chemistry in the Department of Natural Resources and Environmental Sciences at the University of Illinois, Urbana-Champaign, Illinois. He is a fellow of both the American Society of Agronomy and the Soil Science Society of America and holds the Marion L. and Chrystie M. Jackson Soil Science Award from the Soil Science Society of America. He served as associate editor of the *Soil Science Society of America Journal* and chaired the Soil Mineralogy Division of the Soil Science Society of America. He also received the Marion L. and Chrystie M. Jackson Mid-Career Clay Scientist Award from the Clay Minerals Society, where he served as president in 1997–1998.

Dr. Markus Tuller (Soil Physics) received his MS and PhD in civil engineering and water management from the University of Natural Resources and Applied Life Sciences (BOKU) in Vienna, Austria. He is currently an associate professor of soil and environmental physics in the Department of Soil, Water, and Environmental Science at the University of Arizona in Tucson, Arizona, with adjunct appointment in hydrology and water resources. He is the recipient of the Soil Science Society of America Soil Physics Early Career Award. His general area of research is focused on modeling and measurement of mass and energy transport and distribution in porous media. Specific research interests include hydraulic behavior of swelling soils and liner materials, interfacial pore-scale phenomena, liquid behavior in porous media in reduced gravity, and the application of x-ray computed tomography (CT) for porous media research.

Dr. Larry T. West (Pedology) received his BSc and MSc in soil science from the University of Arkansas and his PhD (soil science) from Texas A&M University. He served on the faculty at the University of Georgia for 20 years and is currently with the USDA-Natural Resources Conservation Service as National Leader for Soil Survey Research and Laboratory at the National Soil Survey Center, Lincoln, Nebraska. Dr. West has served as chair of Division S-5 of the Soil Science Society of America.

What Is Soil?

Soil, the extremely thin but precious skin covering our planet, supports all terrestrial life forms and contributes nutrients to aquatic and marine environments. This covering of the unweathered and partially weathered geological formations at the Earth's surface is a unique, fragile veneer. No longer rock nor geological sediment, soil has been altered during the process of soil formation by geological, topographical, climatic, physical, chemical, and biological factors to form a living entity, which inextricably links inorganic or mineral particles with organic matter and biota bathed in a milieu of liquid water and gases. Water, the major constituent of all living entities, is the solvent and conveyor of nutrients, which, together with the solid phase, become the fertile substrate from which all planetary life springs. This nurturing and life-supporting pedosphere zone is a biologically active, porous, and structured medium that effectively integrates and dissipates mass fluxes and energy. In its pristine state, soil is a self-regulating, slowly evolving biogeochemical system that weathers with time, simulating sponge-like behavior and regulating and buffering nutrient supply and water quality and quantity for the growth of macro- and microflora and fauna. Furthermore, it determines the partitioning of water into surface and subterranean groundwater reservoirs.

In addition to its primary role in promoting, supporting, and sustaining all forms of life, soil also acts as a living filter for anthropogenic waste. Soil can recycle water through biochemically mediated processes that cleanse, purify, detoxify, and counteract most toxins and pathogens in polluted waters that would irreparably contaminate and degrade our environment. Despite being the repository of human and animal cadavers, including those from epidemics of pestilence and plague, all but a few vectors have been rendered harmless, and it is seldom, if ever, involved in the transmission of diseases. On the contrary, soil has been the source from which great antidotes to disease and infection, the antibiotics, have been developed.

In ancient times, soil and water degradation, resulting in unsustainable crop production often due to the accumulation of salts, led to the downfall of civilizations. Directly or indirectly, the soil resource impacts, undergirds, and transcends all of society's urban, industrial, and agrarian interests. Current local to global policies and issues on conservation and sustainability, land use, energy, environmental quality, taxation, and food, feed, and fiber production are derived largely from the quality and extent of the available soil resource.

Despite the clearly pivotal role that soil plays in supporting life on Earth, a precise definition of soil is elusive. At this stage, one can say that soil is an evolving, living organic/inorganic covering of the Earth's surface, which is in dynamic equilibrium with the atmosphere above, the biosphere within, and the geology below. Soil acts as an anchor for roots, a purveyor of water and nutrients, a residence for a vast and still largely unidentified community of microorganisms and animals, a sanitizer of the environment, and a source of raw materials for construction and manufacturing. Soil is an essential component of terrestrial ecosystems used by nations as long-term capital to grow and develop. Because this foundation is essential to the life forms within and on it, one requires a fundamental understanding of this elastic, porous, three-phase system (solid, liquid, gas), and its components, processes, and reactions in order to be able to effectively manage and exploit this vital resource. In the words of Roy Simonson "Soil resources are the earthen looms that shape the lives of the people. The more completely they are understood, the better can be the fabric of life woven on these earthen looms" (Wilding et al., 1984).

Every soil consists of one to several layers, called horizons, a few to hundreds of centimeters thick that reflect the physical, chemical, and biological processes that have taken place during its formation. Horizons are composed of natural aggregates called peds, which are made up of associations of mineral and organic particles. Peds and particles are often separated from each other by pores that vary widely in size and shape. In addition, individual peds and particles may be coated by materials such as clay, organic matter, sesquioxides, or precipitated salts. Although the internal structure of peds is not readily visible to the naked eye, their spatial arrangement involving particles and pores (soil architecture) greatly influences soil behavior because

the organization is frequently systematic and related to macropore distribution. At the microscale, soil architecture governs soil water/solute movement and retention, soil structure/porosity, soil strength/failure, mineral synthesis/weathering, movement of toxic and nontoxic wastes, soil/root environments, root growth/proliferation, nutrient transfers, soil erosion, and oxidation/reduction reactions.

What Are the Soil Sciences?

Soil sciences are a spectrum of Earth sciences that address the importance of soils as very slowly renewable natural resources. They involve the study of soil formation, classification, and mapping; the physical, chemical, biological, and mineralogical properties of soil from microscopic to macroscopic scales of resolution; as well as the processes and behavior of soil systems and their use and management. Soils are integrative links between the atmosphere, biosphere, lithosphere, and hydrosphere. Soil sciences provide tools to integrate the components of Earth science systems, expanding knowledge of the causes and effects of spatial variability, and to take a more holistic approach to the dynamic processes affecting ecosystems.

Soil sciences focus primarily on near-surface processes that govern the quality and distribution of soil resources relative to landform evolution (geomorphology), geochemical environment (geochemistry), and organismal habitat (ecology/biology). Pedogenic processes are interactively conditioned by lithology, climate, and relief through geologic time. Soils are welded together into landscapes like chains; processes that perturb and impact higher topographic surfaces directly affect processes on adjacent surfaces below. Pedologists and other soil scientists study the energy flows and mass fluxes, which are the dynamic driving forces of pedogenesis through and over the three-dimensional soil system. They also quantify renewal and transfer vectors for biomass production, rainfall, and dusts, which counter constituent losses through drainage water, lateral interflow, and downslope migration or erosion products.

Soil sciences have their parentage in geology, chemistry, physics, and biology, but for the past 100 years have evolved as an independent, interdisciplinary body of knowledge with strong underpinnings to agriculture and, more recently, the environment. Because of an unparalleled success that soil sciences have enjoyed in helping to bring ample food, fiber, feed, and fuel to the world, the development of the basic soil sciences has evolved primarily as a by-product of research in agriculture, engineering, and the environment. There is growing evidence that the complexity of these problems requires a much broader approach to the science of the soil than can be stimulated by applied research alone. Soil sciences are taking their place alongside basic research efforts in the biosciences, geosciences, and atmospheric sciences to provide the reservoir of fundamental knowledge needed to develop lasting solutions to the challenges of balanced use and stewardship of the Earth. Despite the knowledge accumulated over the past century, Leonardo da Vinci's statement that "We know more about the movement of the celestial bodies than about the soil underfoot" is as true today as it was then. There is need for much more investigation of our most precious resource to stave off the fate that befell our ancestors in the ancient empires of Babylon, Egypt, China, Europe, and the Americas where soil degradation through nutrient loss, erosion, sodification, and salinization together with siltation of rivers and storage facilities laid waste their land and water resources. The ancients were constrained by their limited knowledge of processes driving the system, but we will be judged by generations to come based on our superior understanding of the soil system and the quality and stewardship of our land resources.

Modern parallels of soil and land degradation continue in both developing and industrialized countries. In addition to the problems facing the ancients that are still prevalent, chemical toxicities, irreversible land use conversion, environmental pollution, and desertification are the modern plagues. Sustainability of today's culture is threatened by loss of biodiversity, population growth, and land degradation, leading to enhanced greenhouse gas emissions culminating in global climate change. Land degradation is a complex technical, socioeconomic, and political issue without simple answers. Although soil scientists can provide technical solutions, without implementation as public policy, they are likely to be futile. Currently, public attention is focusing on soil, air, and water quality in efforts to maintain a clean environment. Soil sciences have a major role to play in this arena.

What Is the Purpose of This Handbook?

Handbook of Soil Sciences is a revision of the first comprehensive reference on the disciplines of soil science as practiced today. It contains definitive descriptions of each major area in the disciplines, including fundamental principles, appropriate methods to measure each property, many examples of the variations in properties in different soils throughout the world, and guidelines for the interpretation of the data for various applications (agricultural, engineering, environmental, biological, regulatory, educational, hydrological, biogeochemical). This handbook assembles the current core of knowledge from all fields encompassed within the soil sciences and provides a resource-rich database that will give professional soil scientists, agronomists, engineers, ecologists, biologists, naturalists, and students their point of first entry into a particular aspect of the soil sciences. The contributions also serve those professionals seeking specific, factual reference information. The handbook provides a thorough understanding of soil science principles and practices based on a rigorous, complete, and cutting-edge treatment of the subject compiled by leading scientists in each field. It is designed as a desk reference book.

This handbook has been extended to two books, *Handbook of Soil Sciences: Properties and Processes* comprises five parts dealing with soil physics, soil chemistry, soil mineralogy, soil biology and biochemistry, and pedology. *Handbook of Soil Sciences: Resource Management and Environmental Impacts* discusses soil physical, chemical, and biological interfacial

interactions; soil fertility and plant nutrition; interdisciplinary aspects of soil science; and soil databases.

In the *Handbook of Soil Sciences: Properties and Processes*, the part on soil physics opens with a description of the basic physical properties of soils followed by a treatment of their dynamic properties in relation to tillage and disturbance by machinery. Soil water is discussed, including content/potential relationships, its movement and transfer to the atmosphere both directly and through the plant, and the co-transport of solutes in moving water. The nature of soil structure and its bearing on soil behavior are explored followed by an examination of gas movement under unsaturated conditions. The role of macropores as the superhighway for bypass transport of water and solutes is considered. Thermal regime and heat transfer are discussed. Finally, the heterogeneity of soils is described culminating in an evaluation of spatial variability.

The part on soil chemistry begins with a discussion of the nature and dynamics of soil organic matter. The importance of the soil solution, for transport of nutrients and catalyst for reactions in soil, is then highlighted followed by an evaluation and description of the kinetics of reactions in soils. The reactions taking place when oxygen becomes limiting are then explored followed by a detailed account of soil colloidal phenomena important in predicting the behavior of the finest soil fraction. Ion exchange, sorption, and precipitation reactions are quantitatively treated as a framework to evaluate the behavior of labile constituents in soils. Catalytic reactions promoted by soil and its constituents are examined followed by an account of the effects of acidity and alkalinity on soil reactions and behavior.

Mineralogy of soils is covered in the next part starting with a discussion of the formation and occurrence of minerals in soils followed by three parts in which structure, occurrence, identification, and properties of phyllosilicates, oxide minerals, and poorly crystalline aluminosilicates are discussed. The part on soil biology and biochemistry begins with a discussion of viruses, bacteria, fungi, cyanobacteria and algae, followed by the topic of soil fauna comprising protozoa, nematodes, micro- and macro-arthropods, enchytriads, and vertebrates. The nature, function, and life cycles of each are described. Then the processes mediated by these organisms, including nutrient transformations, are discussed. A major portion of the discussion is devoted to nitrogen transformations because of their importance in soils.

Following a discussion of the geomorphology of soil landscapes and the pedogenic processes and models involved in soil formation, descriptions of the systems used to classify soils are presented in the part on pedology as a framework in which to discuss the soil orders in soil taxonomy and other classification systems. The part continues with a discussion of land evaluation followed by new chapters on hydropedology and subaqueous soils. Thereafter, digital soil mapping and its applications are presented, followed by a discussion of soil change in the anthropocene in which the bridge between pedology, land use, and soil management is built.

In the *Handbook of Soil Sciences: Resource Management and Environmental Impacts*, the new part on soil physical, chemical, and biological interfacial interactions opens with a discussion of the methodology to study metal(oid)s and nutrients at critical zone interfaces followed by insights into the interactions between clay and organic materials in soils. Various aspects of the involvement of nanoparticles in chemical, biological, and hydrological processes are discussed, followed by the effects of mineral and organic colloids on enzymatic activity in soils and its impact on biogeochemical processes. Thereafter, the effects of biophysical, biogeochemical, and biological processes on rhizosphere processes and reactions are discussed. Subsequent chapters deal with mineralogical, chemical, physical, and (micro) biological interactions involved in the turnover and stabilization of organic matter and the transformations of metal(oid)s. The part concludes with a discussion of the physicochemical and biological interfacial processes governing the fate and transport of nutrients and pollutants in soils.

Bioavailability of macro- and micro-nutrients as well as their interactions are discussed in the part on soil fertility and plant nutrition prior to evaluating methods for estimating their potential availability to crops and methods of application as fertilizers. The causes of soil acidity and strategies for its amelioration are also outlined. Finally, the efficiencies of nutrient and water use are discussed. Thereafter, various interdisciplinary aspects of soil science such as salinity, sodicity, water repellency, wetland biogeochemistry, acid sulfate soils, soils and environmental quality, soil erosion by wind and water, land application of wastes, and soil quality and conservation tillage are discussed. Finally, the soil databases available to assess worldwide soil resources are presented and discussed.

I

Soil Physics

Markus Tuller
The University of Arizona

S OIL PHYSICS is concerned with the application of physical principles to characterize the soil system and mass and energy transport processes within the critical zone, which extends from the bedrock to the top of the plant canopy. The exploitation of soil physical principles is not only feasible for natural systems, but also relevant for many industrial and engineering applications such as oil recovery, filtration, ceramics, powder technology, or nanoporous materials. Because soil physical processes are intimately intertwined with biological and chemical processes simultaneously occurring within the same soil volume, the soil physics part is also important for other parts of this handbook.

The second edition of the soil physics part was notably expanded, containing a new chapter about the soil thermal regime and many updates regarding recent theoretical and experimental advances.

Chapters 1 through 3 emphasize the soil solid phase. Included are descriptions and state-of-the-art measurement methods for physical properties of primary soil particles, and the arrangement and organization of primary particles into an overall structure of solids and pore space. At first, soil is considered as static to facilitate definitions of particle density, shape, size, surface area, bulk density, and porosity. Later, the mechanical properties of soils and dynamics induced by tillage operations and temporal variations due to natural and anthropogenic actions are thoroughly examined.

Soil water is the primary focus of Chapters 4 and 5, a major part of Chapters 6 and 7, and relevant for other chapters as well. Amount and energy state are the two most fundamental characteristics of soil water that govern many hydrological, biological, and geochemical processes. Air content and gas exchange with the atmosphere, soil temperature, movement of dissolved chemicals, or diffusion of nutrients to plant roots are intimately related to water content. In addition, changes in water content and energy state affect many mechanical and engineering properties of soils such as strength, compactibility, penetrability, or trafficability. Water content is appropriate to describe storage of water, and knowledge about the energy state (i.e., water potential) is needed to describe direction and magnitude of fluxes. Standard and emerging methods for measurement of water content and potential as well as new numerical modeling tools

for steady and transient water flow are provided. Moreover, soil water movement is described in the context of the overall water balance and its key role in the hydrologic cycle.

Transport processes are principally for water, energy, solutes, and gas. Generally, flow laws are related to an appropriate gradient such as for soil water potential, temperature, or concentrations of solutes. The individual descriptions are related to the appropriate measurable quantities to overall mass conversion.

Chapter 6 contains a detailed description of the water and energy balances at the soil–plant–atmospheric interface, which represents a common convergence point for many of the world's problems in food production, water resources, and environmental pollution. Solute transport, the topic of Chapter 7, is of fundamental importance for crop production (i.e., soil quality and fertility) and environmental pollution and sustainability.

Separate chapters are devoted to soil gas transport and the soil thermal regime. While gas movement (Chapter 8) is historically linked to soil aeration relevant for plant growth, in-depth knowledge about gas transport mechanisms is also important for contaminant remediation, the movement of volatile organic chemicals from waste sites, the design of optimal plant growth media for space exploration, and most importantly, the emission of greenhouse gases and associated public concerns with global warming.

The soil thermal regime and heat transport are described in Chapter 9, which is new to the second edition of the soil physics part. Temperature governs numerous biological, chemical, and physical processes occurring in the soil. Plant germination and growth are closely related to soil temperature. Furthermore, soil temperature affects hydraulic transport properties and important environmental processes such as gas exchange between soil and atmosphere, the global carbon cycle, or transformation and transport of contaminants.

Spatial variability, Chapter 10, is treated separately in recognition of the heterogeneity of all soil properties, in fact, of all measurable natural quantities. In soil science, the development of the quantitative aspects of variation is necessary for both the description of the processes and for forecasting future events. This has been a rich area for coupling soil physical processes with other areas of soil science and remote sensing.

1

Physical Properties of Primary Particles

Joseph M. Skopp
University of Nebraska

This chapter discusses the following physical properties of primary particles: particle density, particle shape, particle size distribution (PSD), and surface area. The definitions and ideas behind these properties have built into it the concept or assumption of discrete primary particles as the primary soil constituent. If organic matter or amorphous materials and cementing agents are abundant, then the importance of primary particles is reduced. In either case, the arrangement or packing of soil particles and these "glues" that control most physical properties of the soil rather than a complete description of the primary particles will be presented in this chapter.

1.1 Particle Density (ρ_p)

1.1.1 Definition

The particle density represents one of the fundamental soil physical properties. One can define particle density as the mass of soil particles divided by the volume occupied by the solids (i.e., excluding voids and water). Typical values for mineral soils range from 2.5 to 2.8 Mg m^{-3} with some soils within the broader range of 1.0–3.0 Mg m^{-3}. The standard value of 2.65 Mg m^{-3} applies only to mineral soils dominated by quartz. Particle density provides few insights into soil physical processes. Consequently, one frequently overlooks the errors associated with particle density. However, its value enters into a variety of calculations of more interesting soil properties (e.g., porosity and PSD).

1.1.2 Typical Values–Mineral, Whole Soil

Each individual soil mineral has a characteristic particle density. Values for different minerals can be found in Klein and Hurlbut (1985). Quartz, a predominant soil mineral, has a value of about 2.65 Mg m^{-3}, which is why this value is frequently given as representing all soils. In contrast, gypsum, biotite, and hematite have values of 2.32, 2.80–3.20, and 4.80–5.30 Mg m^{-3}, respectively. The particle density of a soil is a weighted average over the distribution of soil minerals present.

A determination of particle density may be for individual minerals, size fractions, or the soil as a whole. Organic matter removal may take place in order to reduce variation. With standard procedures and removal of organic matter, a propagated error of less than ±0.01 Mg m^{-3} is possible. (Propagated error is the combination of all instrument errors when making a determination of a soil physical property.) Generally, determinate errors (i.e., biases) play a greater role in the analysis of particle density than indeterminate errors (i.e., random errors).

Perhaps, the most interesting question in the determination of soil particle density is the role of organic matter (with a typical density of 1.0 Mg m^{-3}). Most standard methods remove organic matter. Thus, the particle density reflects only the mineral phase. This value is the best value for use in particle-size analysis. However, it may not be the best value for calculating porosity. Including organic matter means that changes in soil management may change this particle density.

1.1.3 Measurement Methods—Water Pycnometer, Air Pycnometer, Other

Three methods of determining particle density will be examined. Other methods are discussed by Flint and Flint (2002). The most common determination of a soil's particle density uses a pycnometer or some variation. A pycnometer is any device that can be made to retain a reproducible or measurable volume. The soil sample is introduced into the pycnometer and the displaced volume of a fluid is determined. Water is typically the displaced fluid but air can also be used.

The water pycnometer method generally requires the removal of organic matter prior to use. This reduces problems with trapped air and decreases variability. The water pycnometer method requires good temperature control (Blake and Hartge, 1986).

An alternative air pycnometer procedure uses a gas as the displacing fluid and the ideal gas law to calculate the volume of solids. The principles of an air pycnometer are straightforward but care must be taken to prevent temperature changes. The air pycnometer does not require the removal of organic matter, which is particularly valuable when the total porosity (or total void space) or air-filled porosity is required without knowing soil bulk density or water content.

A less common method of determining particle density uses a vibrating tube (Elder, 1979), which is filled with a solution or suspension. The resonant frequency of the vibrating tube provides a very precise means of determining the density of the suspension.

1.2 Particle Shape

1.2.1 Definitions–Shape Factors, Fractals

Particle shape influences specific surface as well as particle-size analysis and has a strong influence on the packing of particles and soil strength, as well as transport properties. Unfortunately, particle shape is a difficult property to measure and few determinations exist in the literature. Recent articles by Jones and Friedman (2000), Santamarina and Cho (2004), and Cho et al. (2006) show the range of soil properties that are influenced by particle shape.

A variety of terms exist for defining particle shape. Some of the definitions require reference to a figure of an ideal particle (Figure 1.1). Let L, B, and T represent the length, breadth, and thickness, respectively, of a particle. Then, Heywood (1947) defines the following:

$$\text{Flatness ratio} = B/T,$$

$$\text{Elongation ratio} = L/B.$$

Other dimensionless terms are as follows:

$$\text{Sphericity} = \frac{\text{surface area of equivalent sphere}}{\text{actual surface area}},$$
FIGURE 1.1 Ideal individual soil particle. (After Heywood, H. 1947. Symposium on particle size analysis. Trans. Inst. Chem. Eng. 22:214.)

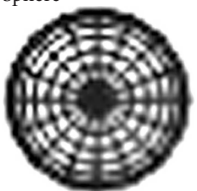
$$\text{Circularity} = \frac{\text{circumference of circle with same area}}{\text{actual perimeter}},$$

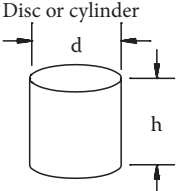
$$\text{Rugosity} = \frac{\text{actual perimeter}}{\text{circumference of circumscribing circle}}.$$

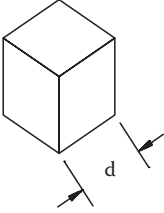
These last two terms work best for a 2D image or the projection of the particle outline onto a flat surface.

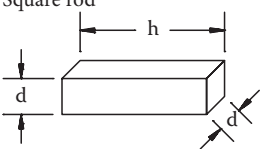
A microscopic picture of soil describes either the solids or the voids. A simple picture of the solids might be a sphere or cube while that of the voids might be a cylindrical tube or a slit between two flat surfaces. These pictures or physical models of the soil make it possible to deduce relations describing surface area, packing, water retention, or water movement.

It is possible to apply these ideas to models that are not simple geometrical figures. Here, a "characteristic length" replaces the edge length of a cube and a dimensionless shape factor (C_k) describes the deviation of the geometry from simple geometries (e.g., Table 1.1). These two factors are used to describe the area and volume as

$$A = C_2 L^2 \quad \text{and} \quad V = C_3 L^3, \tag{1.1}$$








where
  L is the characteristic length
  C_2 or C_3 is the shape factor for area or volume, respectively

For a cube, if L equals d (the length of an edge), find $C_2 = 6$ and $C_3 = 1$. Examples of C_2 and C_3 for other shapes are in Table 1.1.

TABLE 1.1   Shape Factors for 3D Physical Models with L = d

Geometry	Area	C_2	Volume	C_3
Sphere	πd^2	Π	$\pi d^3/6$	$\pi/6$
Disc or cylinder	$(\pi dh + \pi d^2/2)$	$(\pi h/d + \pi/2)$	$\pi d^2h/4$	$\pi h/4d$
Cube	$6d^2$	6	d^3	1
Square rod	$2d^2 + 4dh$	$2 + (4h/d)$	d^2h	h/d

Two particles differing in size may or may not have the same shape. Typically, weathering or size reduction changes not only the total dimension but also the shape factor.

1.2.2 Measurement Methods

At least three methods exist to examine particle shape or shape factors. The first is direct observation under a microscope using an image analysis system (Davis and Dexter, 1972). Commercial image analysis systems exist that automatically provide output of shape factors or similar properties.

The second method is an indirect technique obtained from the variation of viscosity with the concentration of suspended particles. Increasing the solid concentration causes the suspension viscosity to deviate from pure liquid viscosity. These deviations are dependent on particle geometry as well as on concentration of the suspension. The viscosity of the suspension (η) and the viscosity of pure solvent (η_s) usually behave as follows:

$$\eta/\eta_s = 1 + Kf, \qquad (1.2)$$

where
  f is the volume fraction of suspended material
  K is an empirical constant, which is a shape parameter

This relation for spherical particles first appears in Einstein (1906). K = 2.5 is a constant for spheres but changes with the shape of the particle. Kahn (1959) applied this technique to examine the shape of clay particles. Similar techniques (Egashira and Matsumoto, 1981) provide estimates of a/b (the ratio of major to minor axis) for montmorillonite (200–300), kaolinite (15–25), and mica (10–20).

The third method of particle-shape analysis uses the scattering characteristics of light passing through a dilute soil suspension and relies on measurements of the angles of scattered light. Instruments commercially available for particle-size analysis can be used. This is an active area of research since particle shape has an influence on the accuracy of particle-size analysis based on light scattering (Naito et al., 1998).

1.3 Particle Size Distribution

1.3.1 Definitions

PSD is the most fundamental physical property of a soil and defines soil texture. The particle sizes present and their relative abundance sharply influence most physical properties.

Soil particle size (or effective diameter) provides the basis for a classification system. A range of diameters may be given a

special designation (e.g., 2.0–1.0 mm is "very coarse sand"). The ratio between the upper and lower bound is approximately 2 and particles within a given size range are called "soil separates." The size boundaries vary with country or discipline. Comparisons of the names given to a size range are given elsewhere (Gee and Bauder, 1986; Sheldrick and Wang, 1993).

The phrase "equivalent diameters" emphasizes the role of the measurement technique in determining particle size. If identical particles are measured by different techniques, they may appear to have different diameters. It is conceivable that two soils with identical PSDs (as determined by a single method) will show differences in other physical properties due to distinct particle shapes.

Defining the diameter of an irregularly shaped particle is not trivial. A single parameter, the diameter, characterizes a smooth sphere. The symmetry of the sphere and its smoothness mean that no other information is needed to describe it. Distorting the sphere (i.e., into a jelly bean shape) results in at least three possible diameters. Some particle-size analysis methods may orient the particle into a preferred direction (e.g., settling of a particle in a liquid). Other methods (e.g., image analysis) may observe several possible orientations.

1.3.2 Typical Distributions

Typical data for a variety of soils are presented in Table 1.2. Interpretation of particle-size analysis data requires either the drawing of graphs or the calculation of summary coefficients, which are discussed in Section 1.3.7.

Graphs of a PSD typically select the dependent variable as either the cumulative fraction up to a size limit or incremental fraction of soil in a size interval. The incremental fraction (F_i) is usually the mass of particles within a size interval (X_{i-1} to X_i) divided by the total mass of solids, with the index i specifying the size interval. The cumulative fraction (G_i) is the sum of all fractions for particle sizes less than the X_i value.

A typical graphical expression of PSD uses the logarithm of particle diameter (Figures 1.2 and 1.3). Soils frequently show a lognormal distribution of particle sizes, so that a graph of fraction versus the logarithm of particle diameters appears to be normally distributed. The shape and position of the lines provides qualitative information about the soil texture.

Alternative methods of representing the fraction include volume fraction and number fraction. Typically, conversion between distinct types of fractions may be necessary to compare distributions obtained with different methods. In these cases, the assumption is made of spherical particles and a standard particle density. It is important to understand how the method being used represents the PSD.

1.3.3 Dispersion and Fractionation

Particle size analysis (sometimes called mechanical analysis) consists of isolating various particle-size increments and then measuring the abundance of each size interval. Most methods accomplish this in two steps. First, the soil is dispersed or separated into individual primary particles. Second, the dispersed sample is fractionated, or the amounts of each size interval are measured.

There are three objectives of dispersion: (1) removal of cementing agents, (2) rehydration of clays, and (3) physical separation of individual soil particles. It is sufficient to recognize that organic matter and amorphous minerals are the primary bonding agents. When either of these are present in large amounts (e.g., histosols, andisols, or oxisols), then dispersion may be difficult or meaningless. Generally, soil dispersion is carried out using a combination of chemical and mechanical means (Gee and Bauder, 1986; Loveland and Whalley, 1991; Sheldrick and Wang, 1993; Gee and Or, 2002).

It is important to recognize that the fraction of soil that is a single size cannot be determined. What is detected is the fraction of soil within a particular particle-size interval or the cumulative fraction of all particles less than a given size. The use

TABLE 1.2 PSD of Soil Samples

| Soil Series | Sand | | | | | Silt | | | | Clay |
	Very Coarse 2–1 mm	Coarse 1–0.5 mm	Medium 0.5–0.25 mm	Fine 0.25–0.10 mm	Very Fine 0.1–0.05 mm	Coarse 50–20 µm	Medium 20–10 µm	Fine 10–5 µm	5–2 µm	2–0 µm

FIGURE 1.3   Cumulative frequency graph of PSD.

of sieves or sedimentation (e.g., pipette or SediGraph) typically determines the mass fraction (mass of particles in a size interval divided by total mass). Microscopic counting (e.g., image analysis systems or Coulter counter) results in a number fraction (number of particles in a size interval divided by total number of particles). Photometric techniques (e.g., FlowCAM®) typically determine the area fraction. Other methods result in volume or line fractions depending on the sensing procedure. A second complication of comparing PSDs from different methods is the manner in which the particle diameter is determined. In some cases, this is done directly (e.g., image analysis), rely on settling times (e.g., SediGraph), or diameter inferred from volume or other properties (e.g., Coulter counter). Thus, while all the methods are capable of observing PSDs, not all the methods provide results that are equal or directly comparable.

1.3.4 Sieving

The process of sieving is that of placing the particles on a pattern of holes. Small particles may fall through while the sieve retains the larger particles as the sieve is agitated. Either air or water may be the fluid to support the particles as they sort on the sieve. Dry sieving has a lower practical limit of about 50 μm, while wet sieving can separate smaller particle sizes. Changing the fluid can be expected to change the observed frequencies. Sieve holes may be square (using a wire cloth mesh) or round, although square holes are most common. The use of sieves with square openings will not result in measurements equivalent to those using sieves with round holes (Tanner and Bourget, 1952).

The use of words such as effective or nominal diameters with sieves is in recognition of the imperfect separation that may occur. Placement of a soil sample on a sieve does not result in instantaneous separation. Several factors influence the time to achieve a fixed level of separation. These factors include sample size, shaking intensity, particle shape, particle size, and hole geometry. Since samples vary in their sieving characteristics, it is best to run a trial sample. Errors on a single set of sieves typically are less than 1%, while comparisons between sieves show random errors of about 4%.

Many of the standard sieve sizes correspond to the class limits for USDA soil separates. Surprisingly, no standard sieve is available for the 50 μm cutoff between the sand and silt separates. Consequently, sieving cannot distinguish this class boundary using standard sieves.

1.3.5 Sedimentation

Below 50 μm, sieving is an inefficient and difficult procedure and for soil samples, sedimentation in water is an alternative procedure. A suspension of the dispersed sample (see Section 1.3.3) is allowed to settle in water, a measurement can be made of the density of particles suspended (mass of particles in a volume of liquid) at a specified depth within the sedimentation cylinder at known times. Variations in the method occur as to the determination of suspension density. In all cases, Stokes's law (Streeter and Wylie, 1975) is central to the derivation of an equation, which relates the time of settling to the size of particle sampled.

Two classic means of determining the density of a suspension exist: hydrometer and pipette methods. In the hydrometer method, the influence of suspension density on a floating object (the hydrometer) is observed. As density decreases (due to settling out of soil particles), the hydrometer sinks. A calibration scale converts the depth of the float (i.e., hydrometer) to the suspension density (expressed as g L^{-1}). The pipette method directly removes a sample from the solution. The concentration of solids is determined by drying a known volume of the pipetted sample. A proper accounting for dissolved salts requires a blank correction.

The hydrometer method uses higher concentrations of soil and may be less accurate than the pipette method. However, the hydrometer method allows repeated sampling at many points

on the distribution (since no sample is withdrawn). Problems in the pipette method due to convection currents near the tip of the pipette, effect of sample removal, and greater potential for operator error make the hydrometer method preferable in some circumstances (Gee and Bauder, 1979).

Stokes's law for the viscous drag on a sphere is combined with buoyant and gravitational forces to obtain a settling equation. The particle shape is also assumed to be a sphere in evaluating the other forces. Combining vertical forces and solving for v (the particle velocity) gives rise to the settling equation:

$$v = 2r^2 g (\rho_p - \rho_w)^a 9\eta, \qquad (1.3)$$

where
    r is the "equivalent radius"
    g is the gravitational acceleration
    η is the viscosity

The particle velocity is the distance traveled divided by the time or x/t. The settling equation allows a particle radius to be calculated at a particular x and t if the particle density and solution viscosity are known. This equation is basic to all gravity sedimentation procedures. Its use necessitates a number of assumptions not only in the derivation but also in the procedures, whereby the experiment is executed and the equation applied (Baver et al., 1972).

Another alternative to determine the suspension density is by gamma-ray attenuation (Karsten and Kotze, 1984). This method has the advantages of not disturbing the sedimentation column and allowing repeated nondestructive sampling over a large number of settling times. Sedimentation by pipette or hydrometer yields a mass frequency as a function of an effective settling diameter.

1.3.6 Coulter Counter

Individual particles can be counted in suspension by measuring the change in electrical resistivity (or conductivity) as particles pass through a small opening. Each particle displaces a volume of solution that is proportional to the signal. Thus, a single particle passing through the opening results in both a volume measurement (for size) and an increase by one in the count of the particles passing (Hurley, 1970). The commercial apparatus is called a Coulter counter and yields a number frequency as a function of a volume (or the equivalent radius of a sphere having the same volume). The range of diameters is typically between 0.4 and 1600 μm (Multisizer 4 COULTER COUNTER®, brochure http://www.beckmancoulter.com/coultercounter/showDoc.doc.do?filename=&fileid=11567).

1.3.7 Light Scattering

When light is passed through a suspension, several interactions can take place. Besides absorption, light can be scattered in a variety of directions. The behavior of the scattered light provides an alternative means to obtain a PSD. Commercial apparatus

may rely on the angle of scattered light or on dynamic measurements in the fluctuation of the scattered light to recover a PSD. The first method relies on the Mie theory and assumes spherical particles. The second method interprets the fluctuations in terms of a distribution of diffusion coefficients. These are interpreted as representing an equivalent spherical particle having the same diffusion characteristics. An example of the use of light scattering for soils can be found in Cooper et al. (1984).

1.3.8 Other Methods

A variety of variations exist to fractionation by settling under the influence of gravity in water. Settling can be speeded up through the use of a centrifuge (Svedberg and Nichols, 1923). Settling can occur in air, called air elutriation (Jensen and Hansen, 1961). The settling equation for air elutriation is the same as previously developed for water except that the velocity is that of the air floating particles up and the viscosity is that of air. Complete avoidance of settling may occur using microscopic methods to count and sort particles. Image analysis in conjunction with microscopic methods can determine particle shape or geometry parameters. Laser diffraction has also been used to obtain a PSD. More recently, acoustic methods have been developed (Guerin and Seaman, 2004). The acoustic methods also have the ability to determine electrical charge properties of soil particles. A variety of additional methods are discussed in the references by Davies (1984), Gee and Bauder (1986), Loveland and Whalley (1991), and Sheldrick and Wang (1993).

1.3.9 Interpretation of Results

A graph can clearly present the elements of a PSD. However, it is desirable to have a single parameter or a set of parameters to express the properties of the distribution. This is the origin of soil texture class that summarizes the particle-size properties in a single term. The phrase chosen depends on the relative abundance of sand, silt, and clay, irrespective of variations within these size ranges (e.g., Figure 1.4). Typical textural triangles and the textural class names are given in Gee and Bauder (1986) and Loveland and Whalley (1991). Note that while the names of three soil separates are similar to the names of textural classes, a textural class name does not limit the sizes that may be present. In other words, a clay texture class contains sand, silt, and clay separates while the clay separate contains only clay-sized particles.

The use of only the total amount of sand, silt, and clay to describe texture results in a bias that lies in the assumption that all particles within the range of the sand (or silt or clay) size are equivalent. For the clay fraction, this is a particularly misleading assumption and is partly responsible for the low correlations frequently observed when clay content is used in regression analysis. Two soils with the same percentage of clay may differ in the amounts of fine versus coarse clay. Additional differences in the shape and mineralogy of particles can also cause variations in soil behavior.

A more interesting approach determines the moments of the size distribution (Folk, 1966). This gives a quantitative measure
FIGURE 1.4 Alternative texture triangle using clay (%) and sand (%) to determine texture class name. For example, a soil with 50% of clay and 30% of sand sized particles would be assigned a textural class name of clay. (Reprinted from Elghamry, W., and M. Elashkar, 1962. Simplified textural classification triangles. Soil Sci. Soc. Am. Proc. 26:612–613. With permission of the Soil Science Society of America.)

of the mean (first ordinary moment), spread (second-order central moment or standard deviation), and asymmetry (third-order central moment or skewness) of a PSD. More importantly, it increases the power of correlative studies relating texture and any other physical, chemical, or biological factors of interest. As an example, the fourth moment of the size distribution has been related to soil compaction (Moolman, 1981).

If the PSD is known to follow a lognormal distribution, then the geometric mean diameter (d_g) and the geometric standard deviation (σ_g) summarize the PSD. These can be estimated from the mass fraction (f_i) of soil that is sand, silt, or clay. Then,

$$d_g = e^{\sum_1^3 f_i \ln(d_i)}, \tag{1.4}$$

$$\sigma_g = e^{\sqrt{\left\{\sum_1^3 f_i \ln^2(d_i)\right\} - (\ln d_g)^2}}, \tag{1.5}$$

where the d_i values are the average diameter of the size interval, $d_1 = 0.001$ mm, $d_2 = 0.026$ mm, and $d_3 = 1.025$ mm. See Shirazi and Boersma (1984) for more details. The equations above can be generalized if more than three soil separates have been measured and can be used even if the PSD does not follow a lognormal distribution.

Other parameters exist in the engineering literature and elsewhere to describe a PSD. One approach defines the grain diameter (D_n) at which n% passes through a sieve. While D_{40} represents that size for which 40% of the particles are smaller and 60% are larger.

Various combinations of these D_n characterize the distribution. One example is the uniformity coefficient (C_u):

$$C_u = \frac{D_{60}}{D_{10}}. \tag{1.6}$$

The uniformity coefficient provides information as to how narrow the distribution is with 1 being the minimum when only a single size is present. The second ratio is the coefficient of gradation (C_g):

$$C_g = \frac{(D_{30})^2}{(D_{60} D_{10})}. \tag{1.7}$$

Indirect descriptions of the PSD are possible through the use of an equation or model. These models contain parameters, which in turn characterize the distribution. The problem in using these models is first to determine the parameters; second, to determine the appropriateness of the model; and third, to interpret the parameters.

Two modes of particular interest are the power function and lognormal distribution. The use of a power function suggests an underlying fractal process. Where this applies, the exponent (δ) relates to the fractal dimension (n):

$$\delta = 3 - n, \tag{1.8}$$

and n is between 0 and 3. Tyler and Wheatcraft (1992) applied this technique to several materials and reported n values between 2 and 3. The lognormal model has also been useful (Shirazi and Boersma, 1984). Campbell (1985) shows how to estimate the water-holding properties of soil using lognormal model parameters.

1.4 Specific Surface Area

1.4.1 Definitions

The surface area of the individual particles is an important factor in nutrient or pesticide adsorption, water absorption, soil strength, and soil transport properties. The surface area of a soil has contributions from primary particles, amorphous mineral coatings, and organic matter. These individual contributions may overlap and cancel. Further, the surface area of some expanding minerals may change with the water content and chemical composition of the soil solution.

The surface area is an extensive quantity (i.e., depends on how much soil is present). A more satisfying alternative is the introduction of an intensive quantity, the specific surface, which is either the surface area per mass (S_m) or per volume (S_v). The specific surface per volume will change with soil compaction.

1.4.2 Typical Values—Separates, Whole Soil

Typical values for specific minerals as well as values for whole soils are presented in Table 1.3. Amorphous materials and soil organic matter (SOM) can greatly affect soil values. SOM has been reported to have a specific surface as high as 1000 m^2 g. The whole soil values include the effects of PSD as well as SOM and amorphous mineral levels for temperate zone soils.

TABLE 1.3   Ranges of Specific Surface of Clay Minerals, Soil Components, and Whole Soils Compiled from a Variety of Sources

Soils and Constituents	Specific Surface ($m^2 \, g^{-1}$)
Kaolinite	15–20
Illite	80–100
Bentonite	115–260
Montmorillonite	280–500
Organic matter	560–800
Calcite	0.047
Crystalline iron oxides	116–184
Amorphous iron oxides	305–412
Allophane and imogolite	700–1500
Sands	<10
Sandy loams and silt loams	5–20
Clay loams	15–40
Clays	>25

1.4.3 Methods

Direct measurements usually rely on the adsorption of either a gas (typically N_2 or Ar under high vacuum) or a liquid (historically ethylene glycol; but more recently, ethylene glycol monoethyl ether [EGME] or water) (Pennel, 2002). Either a multi- or monomolecular film is deposited or a gas adsorption isotherm is determined. A critical point in the use of all these procedures is the means by which a multi- or monomolecular layer is obtained. Control of the adsorbed phase occurs through the regulation of the gas phase. With gas adsorption, total pressure is controlled while with liquid adsorption, the use of a desiccator helps to fix both the total pressure and partial pressure of the adsorbed component. In the EGME method (Carter et al., 1986), a mixture of EGME and $CaCl_2$ regulates the vapor pressure of EGME. In water absorption, a separate saturated $LiNO_3$ solution regulates the relative humidity. The $LiNO_3$ and EGME methods are convenient procedures for soils. However, both methods are sensitive to variations in temperature. Values for specific surface vary with the method used.

The gas adsorption isotherm frequently takes the form of the BET equation (Brunauer et al, 1938). Here, pressure (P) is varied and the volume of adsorbed gas (V) is observed, all at constant temperature. The two are related as follows:

$$\frac{P}{V}(P_0 - P) = \frac{1}{V_m C} + \frac{(C-1)P}{V_m C P_0}, \tag{1.9}$$
FIGURE 1.5   Surface coating with adsorbent molecules. Larger molecules will not fit in smaller pores.

where

V$_m$ is the volume of a monolayer

P$_0$ is the gas pressure at saturation

C = $\exp[(E_1 - E_2)/RT]$ where R is the gas constant, T is the absolute temperature, E_1 is the heat of adsorption of the first monolayer, and E_2 is the heat of subsequent layers or the heat of liquefaction of the gas

While this equation is frequently linearized, nonlinear regression should be used to estimate V$_m$ from which the specific surface is calculated. The use of either a gas or liquid to determine specific surface also raises questions about the size and nature (polar or nonpolar) of the adsorbing molecule (Figure 1.5). The smaller molecule can be expected to measure a greater surface area than a large one. Differences in surface area (when using distinct adsorbing molecules) are particularly noticeable when soils contain expanding clay minerals.

Another direct method to determine specific surface examines photomicrographs of primary particles. The classical approach determines the probability of a needle (randomly placed on the photo) either falling within a pore or intersecting the pore edge (Scheidegger, 1960). Current image analysis instrumentation allows this evaluation as part of many software packages. Unfortunately, most PSDs are not detailed enough in the smallest size range to accurately estimate specific surface.

1.4.4 Geometric Models and Regression

Geometric models are used to show how particle size influences specific surface and the general relation of particle geometry
FIGURE 1.6 Effect of particle diameter on specific surface for materials of a single size.

to specific surface. Start with the specific surface, $S_m = A/\rho_p V$, where A is the surface area of solids and V is the volume of solids. Then, A and V are expressed in terms of the shape factors C_2 and C_3 and a characteristic dimension, L:

$$S_m = \frac{C_2}{\rho_p C_3 L}. \qquad (1.10)$$

This relation states that specific surface is the reciprocal of the characteristic length of the particles. The shape factors also influence surface area. Using Table 1.3, for spheres, $S_m = 6/\rho_p d$ while for a disc or flat plate, $S_m = [4 + 2(d/h)]/\rho_p d$. A large d/h ratio corresponds to a flat plate. A small d/h ratio corresponds to a prism or needle-like shape. A ratio of d/h = 1 is identical to the result for spheres (Figure 1.6). The specific surface of fine clays may be one or more orders of magnitude greater than for coarse clays.

Whole soils are best measured directly. In some cases, the amount of clay and knowledge of the type of clay can provide an approximate specific surface. Or and Wraith (1999) presented the following regression equations:

$$S_m = 5.65 \times \%\,clay - 18.9 \text{ for soils dominated}$$

$$\text{by montmorillonite} - \text{kaolinite clays}, \qquad (1.11)$$

$$S_m = 1.87 \times \%\,clay + 6.0 \text{ for soils dominated}$$

$$\text{by kaolinite} - \text{illite clays}. \qquad (1.12)$$

These and all regression equations should be used with care. The method used to measure or calculate surface area must be consistent with the use that will be made for the value.

Soil Structure

Teamrat A. Ghezzehei
University of California, Merced

2.1 Introduction

Soil structure refers to the organization and arrangement of soil particles and the resultant complex maze of pores. It is a composite soil quality that exerts significant control over most physical, chemical, and biological *processes* that occur in both natural and anthropogenically altered soils, including transport and storage of liquids, gases, and heat; penetration and proliferation of roots; microbial life; and decomposition and storage of soil organic matter. It is an inherently complex soil property because the constituent particles are heterogeneous in size, shape, and chemical nature as well as because the mechanisms that bond the particles are diverse. It is a hierarchical organization whereby fine primary particles bond together to form secondary particles and small secondary particles merge to form bigger peds or aggregates. It is also a dynamic soil property, continuously changing in response to various internal and external drivers, including moisture and temperature fluctuations, biological activity, and human intervention. As such it is a concept that spans multiple spatial and temporal scales: the arrangement of colloidal clay particles in a floccule, the arrangement of clods on the surface of a tilled layer, an array of earthworm tunnels, and the variability of soil strength from one point to another are all aspects of soil structure (Dexter, 1988). Due to these complexities, we still lack a truly objective description for it and a universally accepted and quantifiable measure of soil structure does not exist yet (Hillel, 1998).

The importance of soil structure has been acknowledged for most of the recorded agricultural history. For much of this time, it was perceived as the soil *tilth*—the structural state of seedbed resulting from tillage and affecting crop response (Hadas, 1997). For accounts of early writings about soil *tilth* and plowing, see the review by Warkentin (2008) and the citations therein. The Soil Science Society of America (1996) defines soil *tilth* as "the

physical conditions of soil as related to its ease of tillage, fitness as seedbed and its impedance to seedling emergence and root penetration." It refers to the favorable physical state of agricultural soil created by tillage, including balanced infiltrability and water retention, optimal aeration and exchange of gases, low resistance to root growth, resistance to erosion, and favorable conditions for microbial activity (Hadas, 1997). These conditions have in fact been the implicit goals of tillage over the ages. Interest in soil structure also arises from its importance to nutrient storage and cycling. A huge fraction of soil organic carbon is tied in soils as integral component of the structural units. Research in soil structure as reservoir of carbon and a large sink for atmospheric CO_2 has been intensified in recent years because of the importance of these processes to climate change issues (Six, 2004).

2.2 Development and Dynamics of Soil Structure

The concept of soil structure encompasses a broad spectrum of spatial arrangement of primary soil particles (Hillel, 1998; Brady and Weill, 2008). At one extreme, we have *single-grained* structure characterized by random arrangement of sand and silt particles with little cohesion. Sand blown dunes and fresh deposits of loess are examples of single-grained structure. At the opposite extreme, we have large cohesive *massive* structure of clay with no discernible internal features. Between these two extremes, soil particles form *aggregated* structure made of quasi-stable particles of various shapes and sizes. Older soil physics literature and *U.S. National Soil Survey Handbook* (USDA-NRCS, 2007) classify the single-grained and massive soils as *structureless*. For this reason, the concept of soil structure is often used to describe soil aggregates. Soil structure is inherently a dynamic feature that undergoes continuous change. There are two main

processes of soil structural change: (a) processes that lead to increased bonding or aggregation of noncohesive particles and (b) processes that cause fragmentation of aggregates or massive blocks of cohesive materials (such as polyhedral peds of soil-containing clay). These processes can and do occur concurrently, and it is not usually easy to separate aggregation from fragmentation. In the remainder of this section, we will discuss these two processes in depth.

2.2.1 Soil Aggregation

Prior to the 1930s, the concept of soil structure was synonymous with soil texture. A great deal of effort went into correlating soil physical properties with particle-size distributions. One attractive feature of soil texture is that it changes very little with time and as a result it is a reproducible index. However, most primary soil particles do not exist unattached. The vigorous mechanical and chemical forces applied to break bonds prior to textural analysis attest that the concept of "primary particles" does not have much meaning in aggregated soils. At around 1930s, there was a growing interest in agglomeration of soil particles mostly with extensive research focused on flocculation of clay particles to the extent that by mid-1940s soil aggregation became synonymous with flocculation. The following excerpt from a classic textbook *Soil Physics* by Baver (1940) describes the status of soil structure research at that time and what was about to happen afterward:

> Soil aggregation is often confused with flocculation. Numerous studies have tried to describe soil aggregate formation and stability based on observations of flocculation in dilute suspensions. These two are not synonymous. Flocculation is purely chemical process, and stability of the floccules is dependent on the presence of the flocculating agent. Stable-aggregate formation (granulation) requires that the primary particles be so firmly held together that they do not disperse in water. This implies that aggregation requires some form of cementation of the flocculated particles. In the words of Bradfield (1936) 'Granulation is cementation plus!'

For an extensive account of the historical development of the concept of soil structure, consult recent reviews by Warkentin (2008) and Six (2004).

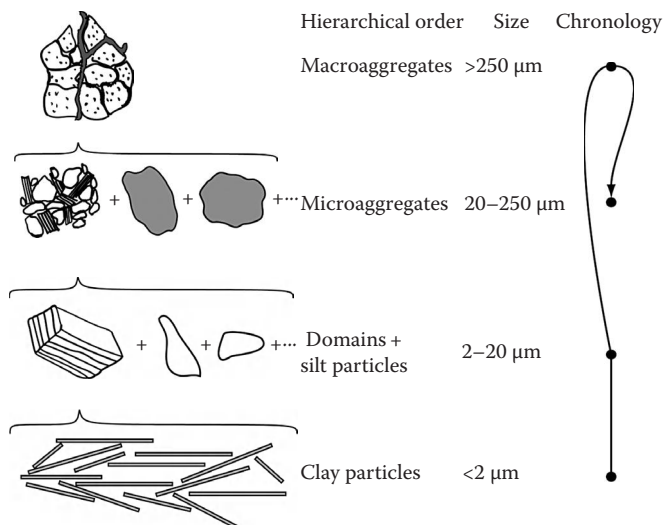
The current conceptual model of soil structure describes soil aggregation as a hierarchical arrangement of particles. First introduced by Tisdall and Oades (1982), the model has been refined continuously by several researchers, including Oades (1984), Hadas (1987), Dexter (1988), and Six (2004). The hierarchies represent size and nature of particles of their respective constituents, nature of the bonds that form them, as well as temporal sequence of their creation. A schematic diagram depicting the hierarchical model is shown in Figure 2.1. The lowest order in the hierarchy involves bonding of primary clay particles into clay domains. Bonding between clay domains and/or with fine silt particles results in clusters. Aggregation of clusters creates


FIGURE 2.1 Hierarchical conceptual model of soil aggregation. (Modified from Dexter, A.R. 1988. Advances in characterization of soil structure. Soil Till. Res. 11:199–238; Six, J. 2004. A history of research on the link between (micro)aggregates, soil biota, and soil organic matter dynamics. Soil Till. Res. 79:7–31.)

microaggregates and bonding of microaggregates results in macroaggregates. In general, each particle of a given hierarchical order is made of 10^2–10^4 particles of the next lower hierarchical order. It is not necessary to have all the orders in every soil. The full spectrum of the hierarchical orders is likely to be present in soils that are rich in organic matter (Oades and Waters, 1991) for reasons that will become apparent in Section 2.2.1.6. Particles of lower hierarchical order are typically denser and stronger than higher order particles (Dexter, 1988). This is due to the fact the smaller order particles do not contain the larger (which are also weaker) pores that exist in higher order particles. An inverse correlation between tensile strength and aggregate size in a given soil was shown by Braunack et al. (1979) and Hadas (1987).

The dynamics of soil aggregation has two basic components: (a) *agglomerating processes* that bring soil particles to close proximity and (b) *binding agents* of organic and inorganic origins that render the inter particle linkages semipermanent. Development of the various hierarchical orders through the interplay between the agglomerating processes and binding agents is described later.

2.2.1.1 Clay Domains (<2 μm)

The basic building blocks of clays are aluminosilicate platelets that have a thickness of a few nanometers and lateral dimensions of several hindered nanometers (Rouse et al., 2004). Electrostatic bonding of these clay platelets (flocculation) forms clay domains, the lowest unit in the hierarchical order of soil aggregation. When clay platelets are brought close to one another, both attractive and repulsive forces can emerge. The repulsive forces arise because the ions that are attached to clay surfaces have identical (positive) charges. The attractive forces have several origins. Clay particles can be attracted to each other when the distance between them becomes so short that they can share the positive ions. This form of attraction is highly dependent on the valency

of the ions. Monovalent ions typically occupy large volumes when hydrated, resulting in very large separation between clay particles. Therefore, clay particles in contact with solution of monovalent ions exist in a *dispersed* state (opposite of flocculated state). In contrast, divalent cations have small hydrated volumes and can be readily shared by adjacent clay particles resulting in a stable and compact flocculation. When clay particles are in contact with acidic solution, the edges of the clay particles develop positive charges. In this condition, the edges of clay particles are attracted to faces of other clay particles, which are typically negatively charged. The face–edge attractions are weaker and more open than the face–face attractions mediated by divalent ions. In general, flocculation is a complex physical–chemical process that results in formation of stable clay domains through the binding of clay platelets by electrostatic attractions. The tendency for clay particles to flocculate is expressed in terms of critical coagulation concentration (CCC)—the minimum concentration of an electrolyte to initiate flocculation of dispersed clay suspension (Hsu and Tseng, 1996; Saejiew et al., 2004; Hsu et al., 2006; Liu et al., 2009). Advanced mathematical and experimental treatment of the formation and stability of clay domains can be found in Smalley (2006). The CCC of soils depends on the type of dominant clay minerals, organic matter content, pH, and cation exchange capacity (Frenkel et al., 1992; Heil and Sposito, 1993a, 1993b; Heil and Sposito, 1995).

2.2.1.2 Clusters (2–20 µm)

Clusters are formed through the bonding of clay domains and/or silt particles. This hierarchical order is so far the least understood and least studied. Clusters are predominantly formed when sand and silt particles are bonded together with colloidal particles, including clay domains, iron and aluminum oxides, and organic colloids (Baver, 1940). Soils that lack colloidal constituents typically do not form aggregated soil structure. Baver (1940) noted that there is a strong correlation between the concentration of 5 µm clay domains and aggregates larger than 50 µm. Baver also noted that the correlation between the concentration of 5 µm clay domains and aggregates larger than 100 µm is much weaker, suggesting that bonding by colloidal clay particles plays important role only at ~50 µm or below. When the mixtures contained organic matter, the correlations between colloidal clay and aggregation were weaker for both >50 and >100 µm aggregate sizes, indicating that colloidal clays play smaller role in the presence of colloidal organic matter. Colloidal organic matter such as mucilages exuded from soil microorganisms can bond clay clusters together and form very stable clusters (Turchenek and Oades, 1979). The bonds between the granular particles are formed upon partially irreversible desiccation of the colloidal particles that act as hardened glue. Sideri (1936) has shown the irreversibility of the bonds between desiccated clay and sand grains. In general, the strength of these bonds depends on the relative abundance of the colloidal particles in relation to silt particles, the size and chemical nature of the colloidal particles as well as wetting and drying history of the bonds.

2.2.1.3 Microaggregates (20–250 µm)

Microaggregates are formed when clusters and silt particles are bound by persistent binding agents (i.e., humified organic matter and polyvalent metal cation complexes), oxides, and highly disordered aluminosilicates (Six, 2004). In the original introduction of the hierarchical conceptual model of soil structure (Figure 2.1), Tisdall and Oades (1982) implied that the transition from lower to higher hierarchical orders is equivalent to chronological order (Six, 2004). Oades (1984) modified this notion and suggested that microaggregates are formed within macroaggregates through the process of fragmentation (see Section 2.2.3; Dexter, 1988; Six, 2004).

2.2.1.4 Macroaggregates (>250 µm)

Macroaggregates are formed from microaggregates that are bound together by weak binding agents such as the hyphae of roots and fungi as well as labile organic compounds derived from exudates of soil microorganisms and roots (Six, 2004). As a result, the strength, porosity, and internal hydraulic conductivity of macroaggregates are strongly influenced by soil management practices. In addition, there is considerable variability of physical properties within individual macroaggregates. Park and Smucker (2005a, 2005b) compared the porosity, hydraulic conductivity, and erosive strength of whole macroaggregates in the size range of 2–9.5 mm and concentric layers within individual macroaggregates. The aggregates used in the study were derived from two soils subjected to three different management practices, namely conventional tillage, no tillage, and native forest. Their findings show that porosity and hydraulic conductivity of whole macroaggregates increase with increasing size, whereas erosive strength decreases with increasing size. Within individual aggregates, the outer layers are more porous, more conductive, and less strong than the inner layers. In addition, they also showed that intensity of soil management decreases porosity, hydraulic conductivity, and erosive resistance.

2.2.1.5 Clods (>25 mm)

Clods are large lumps of soil that may or may not contain discernible particles of lower hierarchical order. In agricultural soils, clods may be formed due to compaction by agricultural machinery. Depending on the state of the soil wetness during compaction and the load of the machinery, the boundaries between macroaggregates may be totally lost or remain as microcracks. The ultimate goal of tillage in such soils is to reverse the creation of clods by liberating the aggregates "imprisoned" within clods (Dexter, 1988). Clods also represent large masses of soil created during desiccation of clayey soils. In this case, the clods need not contain particles of lower hierarchical order (Dexter, 1988). These clods (or peds) and their formation process are of great importance, particularly when dealing with subsoils. Subsoils typically do not have aggregates but show a similarly complex structure. This structure is the major concern when it comes to subsoil compaction since damage to subsoil structure is, in contrast to topsoil (aggregate) structure, considered almost irreversible.

2.2.1.6 Applications of the Hierarchical Model of Soil Structure

The hierarchical soil aggregation is an elegant and compact conceptual model for describing the soil aggregation process across multiple spatial and temporal scales. It has also been used creatively to elucidate some complex features of soil, including (a) the nature of organic matter lost by soil disturbance and (b) multiscale heterogeneity of soil pore space. These are described below.

According to the hierarchical model, microaggregates are formed from clusters that are bound together by relatively stable organic and inorganic colloidal particles. Whereas macroaggregates are formed when microaggregates are held together by weak organic bonds such as hyphae and labile organic matter. Therefore, mechanical soil disturbance (such as tillage) typically degrades the weak links between microaggregates and results in loss of the relative abundance of macroaggregates at the expense of increasing the abundance of "liberated" microaggregates (Oades and Waters, 1991). This state is close to the ideal soil *tilth* because (a) the fine pores within the microaggregates act as reservoirs of water for the seeds, (b) the voids between the microaggregates provide access to oxygen, and (c) the weak bonds between the aggregates exert minimal resistance to seedling establishment (Hadas, 1997). Because microaggregates are formed within macroaggregates (Oades, 1984), the creation of the ideal soil *tilth* is sustainable unless the labile organic matter released during cultivation is continuously replenished. Elliot (1986) used these concepts in describing the disproportionately high loss of labile organic matter during cultivation and his results were instrumental in establishing direct link between cultivation, loss of labile organic matter, and decreased aggregation (Six, 2004).

The hierarchical model of soil aggregation implies the existence of hierarchical pore categories. Elliott and Coleman (1988) proposed the following pore categories: (a) macropores, (b) intermacroaggregate pores, (c) intramacroaggregate or intermicroaggregate pores, and (d) intramicroaggregate pores. Such categorization can be useful in explaining spatial segregation of soil microorganisms. These pore categories house (a) microarthropods; (b) nematodes; (c) protozoa, small nematodes, and fungi; and (d) bacteria, respectively (Six, 2004). These concepts are very powerful because they can also be used to introduce spatial segregation of biochemical processes. For soil hydrologic processes, a slightly different pore categorization is employed and this includes (a) micropores, (b) capillary pores, and (c) macropores (Hillel, 1998). Micropores are generally pores that are less than 1 μm in diameter. Water in such pores is tightly held by adsorptive forces (Tuller et al., 1999) and its mobility is very restricted (Tuller and Or, 2001). Capillary pores range in width from several micrometers to a few millimeters (Hillel, 1998) and hold water that is subject to capillary laws and moves in accordance with Darcy and Buckingham–Darcy laws. The water held in these pores represents the bulk of plant available and mobile water. Macropores are several millimeters to a few centimeters in diameter and may be formed by burrowing organisms and/or

cracking during clay shrinkage. The sum of micropores and capillary pores can also be categorized as interaggregate and intraaggregate pores (Hillel, 1998; Or et al., 2000). These categorizations of soil pores are represented in flow and transport models using multiple overlapping continua. Dual-porosity and/or dual-permeability models, which separate the interaggregate and intraaggregate pores, are the most common forms of such models (Durner, 1994; Nimmo, 1997).

2.2.2 Factors Affecting Soil Aggregation

The formation and stabilization of soil aggregates are influenced by a number of biotic and abiotic factors that operate in concert. Oftentimes, it is difficult to distinguish the role of any particular factor from other factors.

2.2.2.1 Plants and Microorganisms

Soil microorganisms are largely supported by plants and their effect on soil aggregation cannot be viewed separately from the effect of plant roots. The interaction between plants and soil structure has been reviewed by Angers and Caron (1998), who recognized five classes of plants effects on soil structure.

2.2.2.1.1 Mechanical Effects of Root Penetration

When roots grow in soil, the volume occupied by the roots is accommodated by loss of an equal volume of pore space from the surrounding soil (Dexter, 1987b). Most of this displacement occurs at the root tips, which osmoregulate their internal stresses to counter the mechanical strength of the soil that they have to penetrate. The maximum stress that roots can exert ranges from 1 (Dexter, 1987a) to 2 MPa (Goss, 1991). The resulting densification can be modeled as an expansion of a cylindrical or spherical solid object within a homogenous continuum of deformable material (Farrell and Greacen, 1966; Greacen et al., 1968). These models, which were in good agreement with independent experimental observations, show that the density increases exponential from the undisturbed value at a distance away from the root to a maximum value on the root surface. Based on these observations, Dexter (1987a) proposed an empirical model that describes the soil porosity variation over short distances around plant roots:

$$\frac{\phi(r) - \phi_o}{\phi_i - \phi_o} = 1 - \exp\left(-k\frac{r - r_o}{r_o}\right), \qquad (2.1)$$

where
   ϕ is porosity
   r is radial distance measured outward from the center of a
      cylindrical root
   k is an empirical constant that ranges between 0.3 and 0.7
      based on two soils and root radii (Dexter, 1987b)

The subscripts o and i denote values at the root surface and far away from the root, respectively. Whereas these effects of

localized compaction reduce overall infiltration when the roots are living, the nearly vertical macropores left behind and stabilized by decaying roots greatly enhance infiltration (Barley, 1954). Plants with large-diameter, long, and straight roots (such as alfalfa) are known to promote macropore infiltration. The effect of roots on enhanced macropore flow increases with the number of years under plants such as alfalfa with minimal external disturbance (Meek et al., 1989, 1990).

2.2.2.1.2 *Moisture Dynamics Induced by Plants*

Wetting and drying cycles promote soil aggregation as well as fragmentation (see Section 2.2.2.4). Plant roots facilitate this effect by accentuating the wetting–drying cycles. Especially, in soils that exhibit shrink–swell behavior, the pattern and degree of cracking are strongly correlated with the distribution of the root system, spatial pattern of the plants (e.g., row crops vs. random distribution), and the biomass productivity of the vegetation (see Angers and Caron, 1998 and citations therein). Plant roots also promote small-scale moisture heterogeneities, which are efficient in creating small-scale stress imbalances. These stress imbalances can be very instrumental in the creation of microcracks and failure planes within macroaggregates and clods, thereby further promoting soil aggregation. Wetting and drying cycles induced by root hairs and fine roots were shown to cause orientated and compacted clay particles in microenvironments that are 50–200 μm in size (Dorioz et al., 1993).

2.2.2.1.3 *Root Exudates*

Roots promote the creation of stable soil aggregation in their immediate vicinity (rhizosphere) by releasing polymers and nutrient ions that (a) bind soil particles and microaggregates together or (b) support microbial life that generates complex and stable polymers and/or hyphae. Morel et al. (1991) has demonstrated that adding sticky mucilages exuded by maize roots to soil particles promotes instantaneous aggregation. However, these direct effects are typically transient not lasting much longer than 1 month. Consumption of the mucilages by soil microbes that release complex polysaccharides is considered one mechanism that prolongs the effect of root mucilages. In addition, the carbon and nutrients released by roots of many plant species support vesicular–arbuscular mycorrhiza (VAM), whose short hyphae are efficient in binding soil particles together and forming stable soil aggregates (Tisdall and Oades, 1979; Thomas et al., 1986).

2.2.2.1.4 *Carbon Inputs*

In addition to the short-term direct effects of plant roots discussed earlier, plant roots and litter promote long-term soil aggregation and stabilization through continuous supply of organic matter. It is estimated that around 20% of carbon assimilated by photosynthesis is deposited in the soil in the form of exudates and dead roots (Gregory, 2006). Consumption of this organic matter by soil fauna and microbes releases recalcitrant and complex organic molecules that promote formation of stable soil aggregates (Angers and Caron, 1998; Six, 2004).

2.2.2.1.5 *Entanglement by Roots*

Fine and coarse roots can increase stability of soil aggregates by physically entangling and enmeshing aggregates and particles of broad size range. Waldron et al. (1983) conducted shear tests on cylindrical soil columns of 1.2 m diameter—with fully developed root systems of alfalfa and yellow pine. Their experiments showed that shear resistance of the rooted columns was significantly higher than identical columns that were left bare. These large-scale effects are indeed exploited in soil stabilization on sloppy areas using herbaceous plants and trees. Similar effects also operate at much smaller scale. Tisdall and Oades (1982) showed that millimeter-size aggregates are formed and stabilized by the direct entanglement effects of fine roots and root hairs.

These effects of plant roots operate in concert, and it is usually very difficult to accurately distinguish the relative contribution of each effect toward soil aggregation. However, there is ample experimental evidence that demonstrates a positive correlation between vegetation and formation and stabilization of soil aggregates at multiple spatial and temporal scales (e.g., Angers and Caron, 1998; Six, 2004; Gregory, 2006).

2.2.2.2 Soil Fauna

Soil fauna plays an important role in the dynamics of soil aggregation by facilitating transport and breakdown of organic matter and forming burrows that enhance infiltration and fast moisture redistribution following rain or irrigation. The most influential soil faunas are perhaps earthworms. Earthworms are classified as (a) epigeic species that live in the litter layers of forest soils with minimal effect on soil aggregation, (b) anecic species that form and live in extensive burrows, and (c) endogenic species that feed on soil enriched with organic matter (Bouché, 1977; cited by Six, 2004). Networks of earthworm burrows, which are stabilized by the combined effects of compaction and mucous secretions (Edwards and Bohlen, 1996), form a system of fast-flow pathways that enhance infiltration and aeration. Earthworms also play a significant role in the formation and stabilization of soil aggregates by ingesting mixture of organic and inorganic soil materials and excreting the stable mixtures as cast. Numerous studies have shown that these casts are more stable than surrounding soil aggregates (e.g., Six, 2004 and references therein). The stability of earthworm casts depends on the degree of desiccation that they are subjected to, their age, and the nature of the organic matter incorporated in them by earthworms (Shipitalo and Protz, 1987, 1988; Shipitalo et al., 1988; Marinissen and Dexter, 1990). The amount of casting depends on feeding activity of the earthworms. Earthworms ingest larger volumes of soil when the organic content of the soil (food) is lower resulting in more casting. In general, it is estimated that the topsoil of temperate climates passes through the gut of earthworms every 4 years (Gardner, 1991).

2.2.2.3 Inorganic Binding Agents

Inorganic binding agents comprise polyvalent cations (calcium and magnesium) as well as colloidal clays and oxides. Calcium and magnesium operate at the lowest hierarchical order by promoting formation of stable clay domains. As such, their presence is very critical to the overall stability of soil structure at all the higher hierarchical orders. Calcium, in the form of lime, is a common form of soil amendment applied to reclaim dispersed sodic soils (Brady and Weill, 2008). In addition, calcium and magnesium promote microaggregation by forming clay–polyvalent cation–organic matter complexes (e.g., Baver, 1940; Clough and Skjemstad, 2000). Oxides of iron and aluminum can act as binding agents in three ways: (a) adsorption of organic compounds on oxide surfaces, (b) electrostatic attraction between positively charged oxides and negatively charged clay surfaces, and (c) formation of bridges between primary and secondary particles coated with oxides (El-Swaify and Emerson, 1975; Oades et al., 1989; Six et al., 2000). The first two processes act at the scale of microaggregates, whereas the latter process is responsible for stabilization of macroaggregates in oxide-rich soils (Six, 2004).

2.2.2.4 Wetting and Drying Cycles

Most soils experience continuous wetting and drying cycles as a consequence of a number of environmental and internal processes, including precipitation, irrigation, drainage, evaporation, and plant water uptake. These cycles induce soil aggregation and/or fragmentation through a number of processes, including swelling and shrinkage of clays, capillary stresses, as well as transport, deposition, and hardening of organic and inorganic binding agents.

2.2.2.4.1 Clay Swelling and Shrinkage

In soils consisting of substantial amounts of expansive clay fractions, one of the prominent effects of changing soil water content is the concurrent change of soil matrix volume. Nonuniform drying (hence, unbalanced shrinkage) creates internal stresses that eventually lead to cracking. In structureless heavy clay soils, formation of cracks that are several

centimeters wide and deep is a common phenomenon (e.g., Hillel, 1998; Brady and Weill, 2008). Similarly, in aggregated soils, unbalanced shrinkage creates weak planes and microcracks that lead to the formation of microaggregates within macroaggregates (Six, 2004). Swelling of aggregated soil (such as freshly tilled soil) results in joining of adjacent aggregates as they begin to invade one another space. Dexter and coworkers (unpublished data reported in Dexter, 1988) have shown that swelling significantly increases the tendency for spontaneous development of microaggregates in a thoroughly molded soil. In general, swelling and shrinkage can modify soil structure at multiple scales to varying degrees and/or directions (formation vs. destruction). A somewhat related process is freezing- and thawing-induced cracking of heavy clay soils. Farmers in cold regions typically plow clay-rich soils very coarsely. Subsequent freezing and thawing of the big clods create several microcracks and microaggregates (Scott, 2000).

2.2.2.4.2 Capillary Forces

Soils subjected to wetting and drying cycles are known to undergo structural changes by coalescence of adjacent aggregates. This process is primarily driven by strong tensile forces of capillary water (Keller, 1970; Silva, 1995; Or, 1996). Aggregate coalescence is responsible for post-tillage hardening of agricultural soils (Cockroft and Olsson, 2000). Micromorphological studies show that coalescence of aggregates occurs by plastic flattening and fusion of interaggregate contacts without any need for additional cementing agent (Day and Holmgren, 1952; Kwaad and Mucher, 1994). Plastic deformation occurs when the shear stress due to capillary forces exceeds the shear strength of the soil. Flattening of the contact faces was shown to greatly reduce the stresses, thereby restricting unlimited deformation. In an analogous experiment, where external triaxial stress was applied to mimic the effect of capillary forces, McMurdie and Day (1958) showed that soil aggregates behave in a manner similar to plastic grains. Figure 2.2 depicts aggregates that were fused together by capillary forces during multiple wetting and drying cycles. Ghezzehei and Or (2000) used modeled aggregate coalescence as a process driven by interplay between (a) energy liberation from contraction of capillary menisci and (b) energy

(a)   (b)   (c)
FIGURE 2.2   Coalescence of Millville silt loam soil aggregates (2–4 mm) under wetting–drying cycles. (a) Dry soil aggregates separated by mechanical sieving, (b) cluster of aggregates formed by coalescence due to wetting–drying cycles, and (c) partly crushed cluster of aggregates. Note that coalescence took place mainly at the contact points, and most of the aggregates maintained part of their original boundaries. (From Ghezzehei, T.A., and D. Or. 2000. Dynamics of soil aggregate coalescence governed by capillary and rheological processes. Water Resour. Res. 36:367–379. With permission.)

dissipation by viscous deformation of aggregate contacts. The model relies on the viscoelastic nature of wet soil aggregates (Ghezzehei and Or, 2001). An important conclusion derived from this model is the existence of a window of aggregate wetness where the capillary forces exceed the soil shear strength within which aggregate coalescence can occur. The window narrows with each incremental increase in the interaggregate contact area and completely disappears after some critical welding has occurred. Soil densification is traditionally viewed as deterioration of soil qualities that favor plant growth (Cockroft and Olsson, 2000). However, it is increasingly becoming apparent that loss of large interaggregate pores is accompanied by increased connectivity between aggregates leading to enhanced unsaturated hydraulic conductivity (e.g., Carminati et al., 2007a, 2007b, 2008; Berli et al., 2008).

2.2.2.4.3 *Alteration of Organic and Inorganic Colloids*

Slow wetting can promote stabilization of microaggregates by transporting dissolved organic carbon (produced during decomposition of organic matter and/or exuded by plant roots) to the interior of aggregates (Denef and Six, 2005). Drying facilitates localization of soil solutions in the fine crevices and wedges at interparticle contacts as pendular rings, where dissolved organic carbon and inorganic colloidal particles are deposited and form semipermanent bonds (e.g., Reid and Goss, 1982). The surfaces of microaggregates coated with dried organic matter are partially hydrophobic, which reduces their susceptibility to slaking (Caron et al., 1996; Czarnes et al., 2000a, 2000b). Park et al. (2007) compared the stability of aggregates subjected to five wetting–drying cycles with and without dissolved organic matter in the wetting solution. They observed that addition of $0.25\,\mathrm{mg\,g^{-1}}$ glucose soil during each wetting phase maintained the aggregate stability, while the aggregate stability deteriorated in the absence of additional organic-matter supply. Planted soils that were kept at constant water content were observed to have 10%–20% less aggregation than similar soils, which were allowed to periodically dry by plant uptake (Reid and Goss, 1982; Materechera et al., 1992, 1994). The foregoing observations indicate that wetting and drying cycles encourage aggregate stabilization by transporting and altering organic matter.

2.2.2.5 External Stresses

The primary objective of tillage of agricultural soils is to modify the structure so that the resulting morphological and hydrological properties favor optimal flow and storage of water and oxygen as well as minimal resistance to germination and root growth. Concurrently, tillage induces compaction and permanent destruction of inherent structure below the plow layer. A substantial portion of agricultural soil mechanics research has been devoted toward understanding and minimizing the unintended consequences of tillage. Soil structural dynamics as a result of external stresses is described in detail in Chapter 3.

2.2.3 Soil Fragmentation

Soil fragmentation is the flip side of aggregation and it begins with emergence of cracks within aggregates or massive structureless soil volume. Cracks originate in soil when the strain energy imposed by shrinking and swelling or tillage exceeds interparticle bonds (Hallett and Newson, 2001). Soil cracking is generally classified into brittle and ductile cracking. Brittle cracking is applicable for dry soils. Brittle cracking can be viewed as a two-stage process. First, strain energy that exceeds the interparticle bonds is needed to create failure planes. Once the planes are created, the growth of crack obeys a linear elastic law. In this case, the strain energy is stored in the reversible elastic crack.

For wet ductile soils, cracking is accompanied by substantial plastic deformation, which dissipates a significant portion of the strain energy. Unlike in brittle cracking, in ductile cracking the soil at the crack tip has the ability to flow and rearrange. This fluidity results in extra resistance to cracking, which is known as "toughness" in material science (Hallett and Newson, 2001). As a consequence, even if soil strength weakens upon wetting, the increase in toughness results in resistance to cracking. Therefore, both very wet and very dry soils have strong resistance to cracking. Somewhere in the middle, there is a wetness condition where the combined effect of strength and toughness is low and cracking of soils is the easiest. When the energy for cracking originates from shrinkage of clays, the energy also depends on wetness.

2.3 Characterization of Soil Structure

We started this chapter by noting the lack of precise and consistent definition of soil structure and the difficulties underlying this absence of precise definition are apparent from the discussions in Section 2.2. The implications of this vagueness are reflected in the methods employed for characterization of soil structure. In the remainder of this section, we describe four major types of soil structure characterization that are commonly employed in soil physics research. The first group of methods involves qualitative description of soil structure routinely used in soil survey. The second method is related to the morphological and hydrological soil properties that are influenced by soil structure. The third approach reflects the persistence of a given state of soil structure under disruptive forces. And finally, the fourth approach involves various imaging techniques.

2.3.1 Qualitative Description

Soil profile description, as part of soil survey and mapping, involves qualitative characterization of structure in terms of shape, size, and grade (distinctiveness). The terminology and designations used in *Soil Survey Manual* (Soil Survey Division Staff, 1993) are summarized in the following.
FIGURE 2.3 Shapes of soil structure based on the classification in *Soil Survey Manual*. (Adapted from Soil Survey Division Staff. 1993. Soil survey manual. Soil Conservation Service, USDA, Washington, DC.)

2.3.1.1 Shape

The following terms are used to describe the field observable shapes of individual structural units. Schematic illustrations of the various shapes (described below) are given in Figure 2.3.

Platy: Flat and horizontal structural units that commonly occur in clayey soils.

Prismatic: Elongated structural units with flat vertical faces that are matched with the faces of adjoining structural units. The vertices of the vertical faces are angular or subrounded and the tops are typically flat.

Columnar: These are similar to prismatic units, except that the tops are rounded and the vertical faces are also slightly rounded.

Blocky: Equidimensional and polyhedral structural units with flat or slightly rounded faces. The faces of these units are matched with the faces of adjoining units.

Granular: These are similar to blocky units, except that the units are more rounded and the faces are not matched with the faces of adjoining units.

2.3.1.2 Size

Five size classes are used to describe the size of soil structural units: very fine, fine, medium, coarse, and very coarse (Table 2.1). The size limits refer to the smallest dimension of plates, prisms, and columns.

2.3.1.3 Grade

Grade is used to describe the distinctness of individual structural units and the proportion of units that hold together when the soil is handled. Three grades are used:

Weak: It refers to barely observable structural units that disintegrate upon moderate handling.

Moderate: It refers to well-formed and readily recognizable structural units. Most of the units retain their integrity upon moderate handling/disturbance.

TABLE 2.1 Size Classes of Soil Structural Units

	Size Limits (mm)			
Size Class	Platy	Prismatic and Columnar	Blocky	Granular
Very fine	<1	<10	<5	<1
Fine	1–2	10–20	5–10	1–2
Medium	2–5	20–50	10–20	2–5
Coarse	5–10	50–100	20–50	5–10
Very coarse	>10	>100	>50	>10

Source: Soil Survey Division Staff. 1993. Soil survey manual. Soil Conservation Service, USDA, Washington, DC.

Strong: It refers to structural units that are distinctly observable and that separate cleanly when the soil is disturbed.

Qualitative description of soil structure in terms of shape, size, and grade is very valuable in understanding soil genesis as well as in classification and mapping soils. However, there is no objective means of translating these qualitative descriptions to quantifiable characteristics of soil structure and associated morphological and hydrologic properties.

2.3.2 Morphological and Hydrologic Properties

One of the main reasons we study soil structure is because it influences a number of morphological and hydrologic properties of soil that in turn determine storage and movement of various fluids, chemical cycling, and transport, as well as growth of plants and microbes. The most common morphological and hydrologic properties include porosity, bulk density, pore-size distribution, water retention characteristic, and saturated/unsaturated hydraulic conductivity. Determination of these properties requires extraction of *undisturbed* soil cores or better yet use of an in situ method. The notion of "undisturbed soil cores" and the great deal of care and effort invested in acquiring such samples are ultimately an indication of our recognition of soil structure—the organization and arrangement of soil particles—as an important component of soil physical properties.

Numerous attempts to infer the hydrologic properties using intrinsic soil properties (including particle-size distribution, organic-matter content, and soil solution chemistry) have had only limited success because they do not account for the structural component. The well-known method of Arya and Paris (1981) predicts water retention characteristic based on the knowledge of particle-size distribution, particle density, and bulk density. But this method works reasonably well only for soils that are not aggregated. For aggregated soils, empirical equations (also known as pedotransfer functions) are used to relate water retention characteristic and unsaturated hydraulic conductivity functions to soil constituents and descriptions collected during routine soil survey (Bouma and van Lanen, 1986; Schaap et al., 2001; McBratney et al., 2002). The method suffers from lack of physical basis for the prediction and its success greatly depends on the similarity of the database soils to the target soil.

Soil bulk density (ρ_b) is defined as the oven-dry mass of a unit volume of undisturbed soil. It is typically determined by measuring the volume and oven-dry mass of the same volume of soil. For most applications, a core of soil sample is extracted from the desired depth of the target soil using a metal cylinder. Density of soil macroaggregates and clods can be determined by measuring the mass of an individual clod and the volume it displaces when fully immersed in water (with a thin coat of wax to prevent water entry).

Porosity (φ) is a measure of the fraction of total soil volume occupied by pores. It is determined by measuring the total volume of a given soil sample and the volume of its pores. If the average density of the solids is known (which is typically around $\rho_p = 2650 \, kg \, m^{-3}$), then porosity can be readily determined from the bulk density as $\varphi = 1 - \rho_b/\rho_p$.

Water retention characteristic curve describes the amount of water that can be held in a soil by different degrees of capillary forces. Its determination involves concurrent measurement of water content and water potential (capillary pressure) at different degrees of wetness. While porosity and bulk density are measures of the total volume of pores, water retention curve is a measure of the pore-size distribution as well as wetting characteristics of pore surfaces. Water retention curve of structured soils captures the hierarchical nature of soil aggregation (and the resulting pore space). Soils with well-defined macroaggregates exhibit water retention curve with a discernible double-hump feature. Such distinction is represented by considering the pore system as a sum of two overlapping pore systems: one for the interaggregate pores and other for the intraggregate pores.

Hydraulic conductivity describes the water flux through soil to conduct water under unit total water potential gradient. It reflects not only pore-size distribution and wetting characteristics of pore surfaces, but also connectivity between pores. Direct determination of hydraulic conductivity involves measurement of flux density across a volume of soil subjected to known boundary water potentials. The value of hydraulic conductivity decreases by several orders of magnitude when a soil is drained. Therefore, determination of hydraulic conductivity of unsaturated soil is laborious and time consuming. Oftentimes, hydraulic conductivity of unsaturated soil is determined from water retention curve using models that represent soil pores using mathematically tractable representations. Of these, the most common model is that of van Genuchten (1980), which relies on a model of soil pores as bundle of capillary tubes (Mualem, 1976). Recent modifications of this indirect approach (Tuller and Or, 2001) recognize the angularity of soil pores and adsorption of thin films on clay surfaces and provide better predictive capability albeit at higher computational complexity. For more detailed discussion on soil–water relations, see Part I Chapters 4 and 5.

The above-described physical properties are dynamic in nature undergoing continuous change at multiple scales in time as illustrated in Figure 2.4. The data of Silva (1995) shown in Figure 2.4a were derived from columns of Millville silt loam soil subjected to wetting and drying cycles. Figure 2.4b depicts change in interaggregate porosity of Cotto clay soil under three tillage types (Rivadeneira, 1982). The interaggregate porosity, determined as the ratio of the total porosity for the three tillage treatments to the porosity for zero tillage, is plotted as a function of time after tillage. Change in total porosity is often accompanied by change in water retention curves. For the two illustrative examples shown in Figure 2.4, the corresponding evolution of water retention curve is shown in Figure 2.5. The striking feature of these data is that the comparable changes in porosity and water retention curve occurred within a few hours for the Millville silt loam soil while it took several weeks for the Cotto clay. The dynamics of the Millville silt loam soil was driven by capillary forces (Or et al., 2000) where as a complex interaction of various factors (including wetting and drying, plant roots, and microbial activity) may have contributed for the dynamics of the Cotto clay soil.

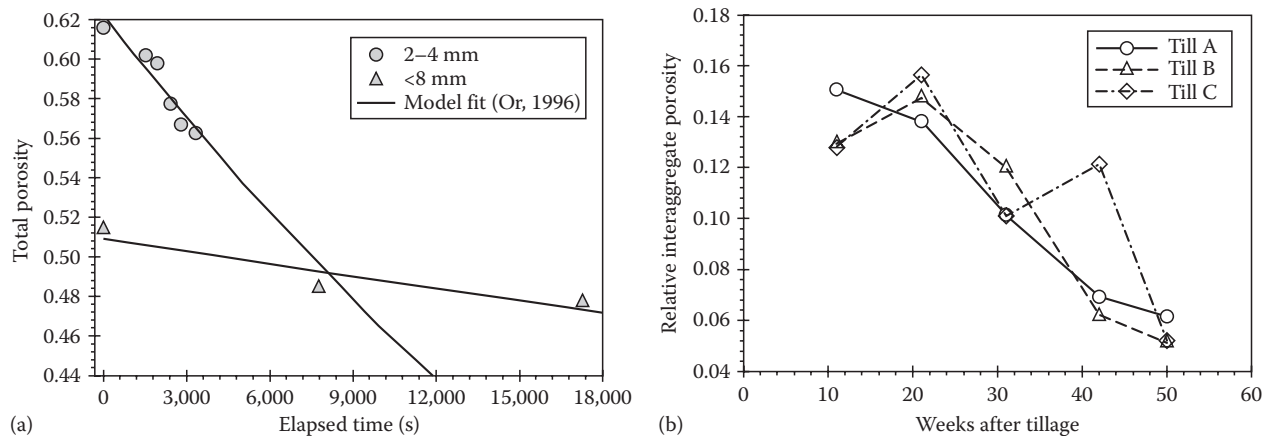
Because of the complexity of factors that are involved in the evolution of soil structure, the physical properties described


FIGURE 2.4 Rate of porosity loss, porosity measurements (a) versus elapsed time since initiation of wetting for two aggregate sizes (From Silva, H.R. 1995. Wetting-induced changes in near surface soil physical properties affecting surface irrigation. Ph.D. Dissertation. Utah State University, Logan, UT.) and relative interped porosity (b) for three different tillage practices versus weeks after tillage. (From Rivadeneira, J. 1982. Changes in physical properties in the plow layer of Coto soil as a function of tillage methods, and correlations with tanier development (in Spanish with English abstract). M.S. Thesis. University of Puerto Rico, Rio Piedras, Puerto Rico.)
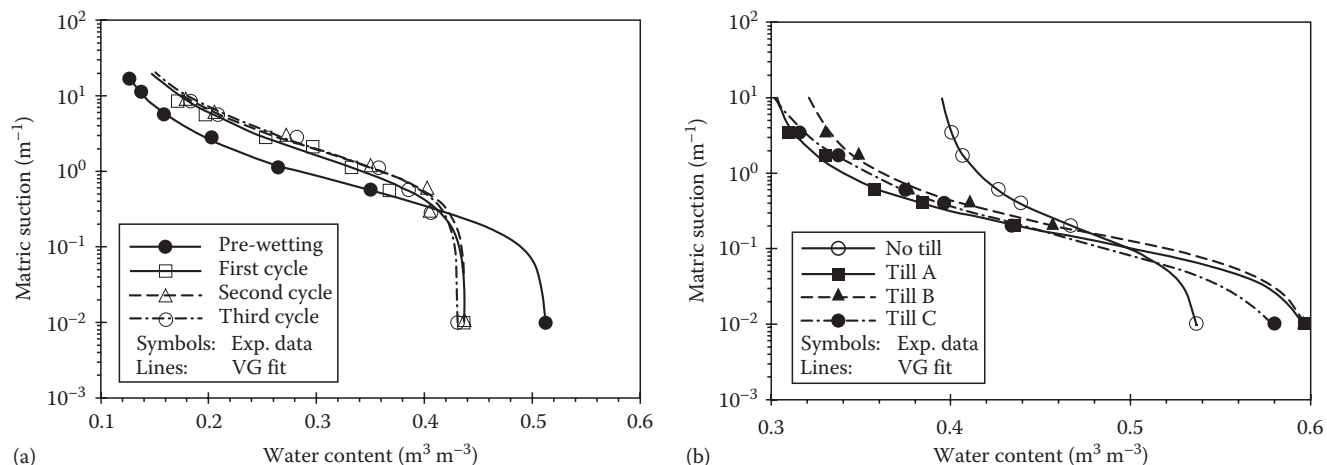

FIGURE 2.5 Comparison of evolution rates and shapes of soil water characteristic curves of two different soil types: (a) Millville silt loam soil before and after three cycles of wetting and drying in a few-hour timescale. (From Silva, H.R. 1995. Wetting-induced changes in near surface soil physical properties affecting surface irrigation. Ph.D. Dissertation. Utah State University, Logan, UT.) (b) Cotto clay soil under no till and three different types of tillage practices after 11 weeks of treatment. (From Rivadeneira, J. 1982. Changes in physical properties in the plow layer of Coto soil as a function of tillage methods, and correlations with tanier development (in Spanish with English abstract). M.S. Thesis. University of Puerto Rico, Rio Piedras, Puerto Rico.) Note that the tilled treatments in (b) correspond to the prewetting loose state in (a).

above are often treated as semipermanent characteristics of soil. Recently, there have been modest successes in predicting changes in soil structure and the associated physical properties. Ghezzehei and Or (2000) used energy-based analysis to develop a model that predicts the evolution of pore size during wetting and drying cycles. The model was subsequently used in a stochastic framework to predict evolution of pore-size distribution and water retention curves (Or et al., 2000). Figure 2.6 depicts evolution of the interaggregate pore space and the corresponding change in water retention after three cycles of wetting and drying. Here, only the interaggregate pore space is considered as dynamic as it directly depends on structure. The intraaggregate pore space is considered as constant as it depends mostly on the textural composition of the aggregates.

2.3.3 Stability of Soil Structure

Aggregate stability refers to the ability of aggregates to persist under internal and external disruptive forces. The disruptive force often impacts pores and/or aggregates of certain sizes only resulting in destruction of one or more hierarchical orders while concurrently forming another hierarchical order. The destruction of a certain hierarchical order is accompanied by destruction of all higher orders. Therefore, when discussing the stability of soil structure, it is very important to be specific at what order the destabilizing forces or processes operate (Dexter, 1988).

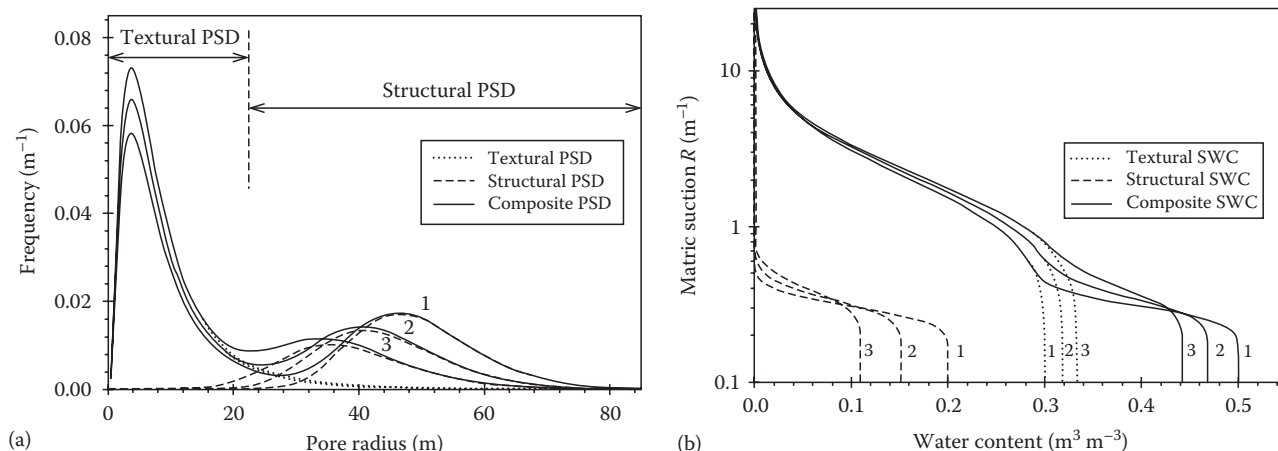
The reaction of soil aggregates to disruptive forces depends not only on the qualities of the soil itself but also on the nature of the disruptive forces. Therefore, the definition of aggregate


FIGURE 2.6 Evolution of (a) soil pore-size distributions and (b) soil water characteristic curves resulting from two cycles of wetting and drying (Figure 2.5a). Numbers represent the wetting–drying cycles (1 is initial; 2 is the end of first cycle; and 3 is the end of second cycle). Dashed lines represent the evolving structural (interaggregate) pore system.

stability and its characterization are linked with the disruptive forces of interest. In general, we can identify two main types of stability: (a) the ability of the soil to retain its structure under the action of water and (b) the ability of soil to retain its structure under the action of external mechanical stresses such as the impact of tillage implements and wheels (Dexter, 1988).

2.3.3.1 Water Stability

Water impacts soil aggregate stability in a number of ways. The initial action of water when aggregates are wetted is slaking, which refers to the disruption of soil aggregates by the action of entrapped air. During rapid wetting of dry aggregates, water enters each individual aggregate through its entire outer surface. This results in weakening of the outer layers of the aggregate, while concurrently the pressure of the air entrapped inside the aggregate rises. If and when the pressure of the entrapped air exceeds the strength of wetted outer layers of the aggregate, the air escapes by breaking the aggregate into smaller fragments as illustrated in Figure 2.7 (Emerson, 1954; Hillel, 1998). The violence of aggregate breakdown by slaking depends on the competition between air-pressure buildup and weakening of the soil strength upon wetting. For the entrapped air to gain pressure, it must be completely enclosed by saturated outer layers and must have sufficiently large starting volume so that subsequent wetting can result in the required gas compression. Emerson (1954) identified a number of factors that determine such pressure buildup. The primary factor is the rate of wetting, which in turn depends on the manner and source of wetting, the surface tension of the wetting liquid, and wettability of the aggregates. For example, aggregates with high-organic-matter content are less prone to slaking because the slight hydrophobicity of organic residues prevents rapid and even wetting of their outer surfaces. Another factor is the initial water content of the aggregates. Moist aggregates are typically less susceptible to slaking because they have smaller portion of their voids occupied by air as well as because preexisting continuous water films lead to diffuse wetting front as opposed to wet thin skin that forms upon wetting of very dry aggregates. Aggregates do not slake during rapid wetting unless the initial water potential is lower than $-1\,\text{MPa}$ (Grant and Dexter, 1986). Slaking produces aggregates that are larger than $250\,\mu\text{m}$ (Oades, 1986). If the air pressure is strong enough to break down the aggregates, slaking produces microcracks that are oriented parallel to the wetting front (McKenzie and Dexter, 1985).

Dry aggregate   Rapid wetting   Slaking
FIGURE 2.7 Slaking of an aggregate rapidly immersed in water. (Modified from Hillel, D. 1998. Environmental soil physics. Academic Press, San Diego, CA.)

Slow wetting can weaken aggregates by creating microcracks. Microcracks can be formed due to differential swelling of soil aggregates, which in turn can be caused by nonuniform wetting of individual aggregates and/or internal heterogeneities. The microcracks do not always join and result in breakdown of the aggregates. However, the creation of a network of microcracks results in considerable reduction in strength (Dexter et al., 1984) making the aggregate susceptible to disruption by other forces. Microcracks induced by the stresses generated by differential swelling on wetting are oriented mainly perpendicular to the wetting front (McKenzie and Dexter, 1985).

On uncovered ground surface, the kinetic energy of raindrop and flowing water can break down aggregates and transport the detached particles. Abrasion by particles suspended in flowing water provides additional scouring power that facilitates the disintegration of wet aggregates (Hillel, 1998).

Characterization of water stability of soil aggregates is conducted by simulating the processes that occur in nature. The most widely employed characterization method simulates the action of flowing water (Kemper and Rosenau, 1986). In this method, a sample of soil aggregates is placed on top of a nest of sieves. The sieves are immersed in water and shaken in a regular up-and-down motion at prescribed rate and vertical distance. The aggregates retained in each of the sieves after a fixed period of shaking are collected and dried in oven. Kemper and Rosenau (1986) suggest starting with 4 g of air-dry aggregates with 1–2 mm diameter and subject them to wet sieving at a rate of 35 cycles min^{-1} and vertical displacement of 1.3 cm for 3 min. Aggregates subjected to this treatment typically prewetted slowly to avoid slaking. Wet sieving provides a distribution of aggregate sizes. Van Bavel (1949) proposed the mean weight diameter (MWD) as a single-valued index of aggregate stability:

$$\text{MWD} = \int\limits_{0}^{x_{\max}} x f(x) dx, \tag{2.2}$$

where

  x is aggregate size
  $x_{\max}$ is the maximum aggregate size prior to wet sieving
  $f(x)$ is the empirical aggregate-size distribution

Before the availability of digital computers, the integration had to be done manually using a graphing paper. To simplify the time-consuming process, Youker and McGuinness (1956) proposed the use of summation in place of the definite integral:

$$\text{MWD} = \sum_{i=1}^{n} \overline{x}_i w_i, \tag{2.3}$$

where

  $i = 1, 2, \ldots, n$ is the index of sieves
  $\overline{x}_i$ is the mean diameter of the ith size class
  w_i is the corresponding weight fraction

MWD computed by summation is typically larger than the value computed by integration, especially if the number of the sieves is as small as the typical nest of five sieves (Kemper and Rosenau, 1986). This index of aggregate stability presupposes that the aggregate sizes are normally distributed. However, aggregate-size distributions reported by Van Bavel (1949) were skewed and Gardner (1956) proposed the use of a log-normal distribution based on additional data. Mazurak (1950) suggested the geometric mean diameter (GMD), which is better at representing a log-normal distribution than MWD:

$$\text{GMD} = \frac{\sum_{i=1}^{n} \log(\overline{x}_i) w_i}{\sum_{i=1}^{n} w_i}. \tag{2.4}$$

The GMD is getting wider use only recently (e.g., Abid and Lal, 2008) because of the extensive manual calculation it involved prior to the age of digital computers (Kemper and Rosenau, 1986).

Stability of soil aggregates under the disruptive energy of raindrops is determined by subjecting individual aggregates to drops in a standardized manner (Hillel, 1998). The fraction of the aggregate that remains intact after a prescribed duration or the number of drops required to completely destroy the aggregate are used as indices of the stability of the aggregate.

2.3.3.2 Mechanical Stability

Mechanical stability refers to resistance of aggregates to external forces such as tillage implements and wind. We can recognize at least three different types of external forces: tensile, compressive, and shear. Tensile forces applied to aggregates of a certain hierarchical order tend to cause failure surfaces between the particles and/or aggregates of the next lower hierarchical order while leaving those low-order aggregates intact (Dexter, 1988). This is generally because internal strength decreases with increasing hierarchical order (Braunack et al., 1979; Dexter, 1988).

Shearing of aggregated soil results in complex behavior that depends on the water content and density of the aggregates. If the density of the structured soil is below a characteristic critical value, the theory of critical state soil mechanics (Kurtay and Reece, 1970; Hettiaratchi and Ocallaghan, 1980) suggests that the stress propagates through the volume of the soil resulting in overall density reduction with disproportionate destruction of larger pores (Dexter, 1988). In contrast, if the structured soil is denser than the critical value, shearing is confined to a narrow band near the source of the stress, rolling of round particles or alignment of platy clay particles can occur. In the latter case, the gross changes in volume occur only in a small proportion of the soil.

Compression (uniaxial or multiaxial) typically results in densification that can extend throughout the volume of the soil. Dexter (1988) recognizes three types of response to uniaxial compression of aggregated soils. Hard (typically dry) aggregates respond to uniaxial compression by rearrangement and frictional attrition at their contacts that leads to overall densification. If the stress is large enough to cause brittle failure of individual hard aggregates, some aggregates are fractured and fragments released from the cracks fill larger voids. If the aggregates are soft, the aggregates deform at their contacts (points of maximum stress) resulting in flattening of contacts (Day and Holmgren, 1952; McMurdie and Day, 1958; Ghezzehei and Or, 2003a, 2003b). Similar flattening of contacts in response to internal capillary forces was proposed by Ghezzehei and Or (2000). The extent and rate of contact flattening (aggregate coalescence) can be related to the rheology of the soil forming the aggregates. Ghezzehei and Or (2000, 2001) showed that wet soils have viscoelastic behavior with the yield stress and apparent viscosity values that decrease with increasing water content.

2.3.4 Imaging Techniques

Imaging provides a direct and objective means of characterizing soil structure. Unlike the above three approaches, it can provide both qualitative and quantitative descriptions. The available imaging methods can be broadly classified into three groups: (a) thin-section micrography, (b) scanning electron microscopy (SEM), and (c) x-ray computed tomography (CT).

2.3.4.1 Thin-Section Micrography

The key developments that led to micrographic methods in soil research were thin-sectioning methods and petrographic microscopy in early twentieth century. The publication of the book *Micropedology* (Kubiena, 1938) introduced standardization of the methods and interpretation on micrographic studies of soil. The most important step of this method is the elaborate and time-consuming process of preparing thin sections for microscopy. For comprehensive description of procedures, consult the *Handbook for Soil Thin Section Description* by Bullock et al. (1985). Briefly, the method involves impregnation of soil pores with low-viscosity resins (such as unsaturated polyester, epoxy, and methyl methacrylate). To ensure complete saturation, this process is often carried out using dry sample under vacuum. After the resin is allowed to harden, the sample is affixed to microscope slide and sliced into thin sections, followed by polishing to remove traces of cutting. The final thickness of the thin section is typically 20–30 μm. Pigmented resins are used to enhance contrast. Thin-section preparation is inherently susceptible to several defects that can make subsequent image interpretation difficult. These include scratches and striations, entrapment of bubbles, contamination by translocated particles, and/or cutting abrasives.

Soil micrograph can be used to directly determine pore sizes and pore-size distributions, pore geometry, as well as aggregate sizes and shapes. Day and coworkers (Day and Holmgren, 1952; McMurdie and Day, 1958; McMurdie, 1963) used soil micrography to visualize deformation and welding of soil aggregates and accompanying the evolution of interaggregate porosity. However, a single two-dimensional (2D) cross section does not provide a complete picture of the three-dimensional (3D)

features of soil structure. Some common problems of 2D images include the following: (a) a given pore can appear to have different sizes depending on where the cutting plane passes through, (b) a wavy tubular pore (such as earthworm cast) can intersect the cutting plane multiple times and appear as a series of circular pores, and (c) adjacent particles (or aggregates) may appear disconnected.

2.3.4.2 Scanning Electron Microscopy

Compared to optical microscopy, SEM provides far more superior resolution albeit for much smaller field of view. Therefore, the application of SEM has been mostly used to study the microstructure of clay domains and their associations with cations and organic matter (Chen and Banin, 1975; Chenu, 1993; Skjemstad et al., 1996). Recently, a variation of SEM that utilizes flash freezing (Cry-SEM) has been successfully used to visualize the microstructure of rhizosphere (Gregory, 2006; Refshauge et al., 2006; McCully et al., 2009). These methods are instrumental in further understanding the role of roots and mycorrhizae in the development of soil structure (see Section 2.2.1).

2.3.4.3 X-Ray Computed Tomography

The application of 2D x-ray imaging in soil structure has been limited because of its inability to resolve the compounded effect in the third dimension. For example, Farrell and Greacen (1966) and Greacen et al. (1968) used medical x-ray facility to study soil density variations around a penetrometer inserted into a uniform soil. These observations were later used to develop conceptual and quantitative model of soil–root interactions by Dexter (1987a, 1987b).

In contrast, x-ray CT was adopted for soil research in early 1980s, soon after the technique was developed for medical applications. A thorough review of the application of x-ray CT in soil science and underlying principles is given by Taina et al. (2008). The method relies on the attenuation of x-ray as it passes through a subject medium (such as soil). The degree of attenuation is correlated with the bulk density as well as the actual and/or effective atomic weights of the materials encountered along the path. By integrating multiple projections of the same cross-sectional plane, tomographic reconstruction produces an effective density map (gray-scale image) of the cross section. Because these images are acquired noninvasively, it is possible to obtain several images of adjacent thin layers. This method has allowed visualization of undisturbed soil structure and the associated pore network in full 3D. X-ray CT have been used to quantitatively characterize porosity, pore geometry (diameter, perimeter, and area), tortuosity, and 3D hydraulic radius (e.g., Anderson et al., 1990; Perret et al., 1999; Gantzer and Anderson, 2002; Rachman et al., 2005). This method has also been successfully used in investigations of soil structural evolution due to disruptive forces such as tillage and erosion (Rogasik et al., 1999; Gantzer and Anderson, 2002; Lipiec and Hatano, 2003). Attempts to reduce the massive 3D x-ray CT description of soil structure to concise and mathematically tractable form have been performed using mathematical morphology (e.g., Pierret et al., 2002) and mass fractals (Rachman et al., 2005).

A key step in interpretation and quantification of x-ray CT imagery is segmentation—the process of classifying the images into two or more types of regions (e.g., voids, solids, water, and roots). The simplest approach is binarization of the gray-scale image (e.g., into voids and solids) by setting a global threshold in the histogram of the gray scales. This method is prone to miscategorization due to overlapping gray values common to the two populations (Taina et al., 2008). Alternative approaches include locally adaptive thresholding, region-growing methods (that assume voxels belonging to an object are connected and similar), probabilistic fuzzy clustering, and Bayesian methods (see Iassonov et al., 2009 and reference therein). Iassonov et al. (2009) used 14 segmentation algorithms that fall under global and locally adaptive approaches to derive soil porosity using common CT images. These algorithms yielded in vastly varying results and only a few gave promising results suggesting the need of reliable, consistent, computationally efficient, and automated algorithms applicable to a wide range of porous materials.

2.4 Concluding Remarks

Soil structure is a term widely used in all branches of soil science. The concept of soil structure is well established and has been continuously evolving. However, a precise definition of soil structure has not been adopted so far. Current definitions in various fields of soil research are summarized here.

For an agronomist, it refers to the quality of soil that relates to crop growth and productivity and may refer to water-holding capacity, ease of tillage, and suitability for root growth and microbial life. The agronomy-oriented literature on soil structure is replete with empirical correlations between various soil amendments (including lime, organic matter, and synthetic polymers) and the resultant changes in soil properties that depend on structure (such as porosity, water retention, and hydraulic conductivity).

For a conservationist, soil structure refers to resistance to water and wind erosion. Soil erodibility, a measure of the inherent susceptibility of any given soil to erosion, is closely tied to the stability of soil aggregates. In fact, the concept of aggregate stability was originally introduced to characterize soil erodibility (Yoder, 1936). Most aggregate stability characterization methods are designed to determine the ease with which particles can detach from soil aggregates by raindrop impact, flowing water, and/or wind. But it is still difficult, if not totally impossible, to predict erodibility based on the knowledge of aggregate stability because the methods of characterization cannot replicate all aspects of the erosive forces (Bissonnais, 1996).

For biogeochemists and global-change researchers, soil structure is viewed in association with nutrient storage and cycling (van Veen and Kuikman, 1990; Juma, 1993; Ladd et al., 1996). Soil structure is not only a product of organic carbon, but also a venue where carbon is stored and preserved from decomposition and released to atmosphere. Soil structure controls storage and cycling of organic carbon through its influence on the pore sizes that can be inhabited by soil organisms

as well as availability of water and oxygen. Large quantities of readily decomposable organic matter can be found in the vicinity of starving microbial populations but remains inaccessible to decomposers through chemical and physical protection (van Veen and Kuikman, 1990).

A common theme that has been developed within these diverse points of view is that the concept of soil structure spans multiple scales in time and space. The processes and factors involved in forming structure vary considerably with spatial and temporal scales. Similarly, the properties and functions influenced by soil structure vary depending on the scale of observation. The basis for this multiscale concept is the hierarchical model of soil aggregation, which has been undergoing continuous refinement and elaboration since its inception by Tisdall and Oades (1982). However, the interrelationships between the various factors involved in the creation and stabilization of soil structure on one hand and the numerous soil properties that are directly determined by soil structure on the other hand are very complex and rarely quantified. To make the concept of soil structure a useful descriptive as well as predictive tool, there is a need for quantification of the hierarchical conceptual model and the various factors that it entails.

Mechanics of Unsaturated Soils for Agricultural Applications

Rainer Horn
Christian-Albrechts-Universität zu Kiel

Stephan Peth
Christian-Albrechts-Universität zu Kiel

3.1 Introduction

Soils undergo intensive changes in their physical, chemical, and biological properties during natural soil development and as a result of anthropogenic processes such as plowing, sealing, erosion by wind and water, amelioration, excavation, and reclamation of devastated land. In agriculture, soil compaction as well as soil erosion by wind and water are classified as the most harmful processes. Irrespective of land-use systems, soil deformation as the sum of soil compaction and shear processes leads to numerous environmental changes affecting soil quality for crop production, soil biodiversity, filtering and buffering functions of soils, soil-water household components, trace gas emissions, soil erosion and nutrient export, and related off-site effects (Figure 3.1).

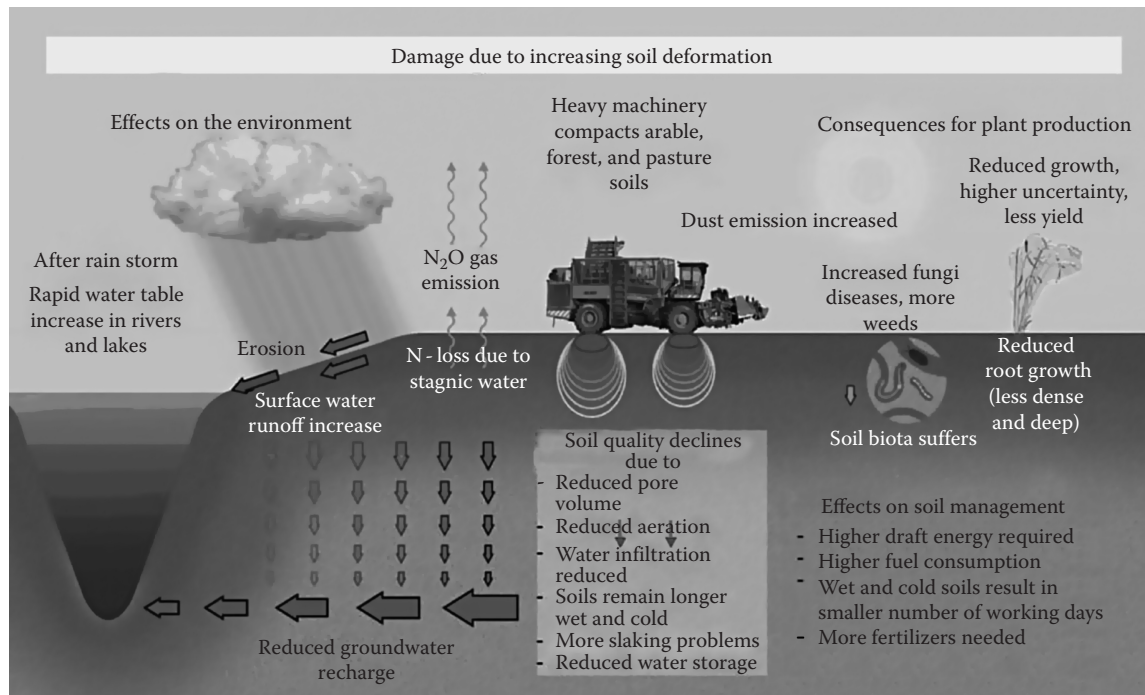
In forestry, normal plant and soil management, tree harvesting, and clear-cutting also affect site-specific properties, including organic-matter loss and groundwater pollution and gas emissions, which have the potential to cause global changes. Furthermore, soil amelioration especially by deep tillage prior to replanting often causes irreversible changes in properties and functions. These interrelationships have been described by Jayawardane and Stewart (1994), Soane and van Ouwerkerk (1994), Horn (2000), and Horn et al. (2006) as well as by Birkas et al. (2004). Oldeman (1992) showed that about 33 million ha of arable land are already completely devastated by soil compaction in Europe alone while the total area of degraded land worldwide exceeds about 2 billion ha. Physical (soil erosion and deformation) and chemical processes are responsible for about 1.6 and 0.4 billion ha of degraded soils, respectively. Worldwide population growth will reduce the average area per person for food and fiber production from 0.27 ha today to <0.14 ha within 40 years, and even if the advances in technological developments continue to grow, more concern has to be made in order to prepare enough food for the population worldwide. Consequently, a more detailed analysis of soil and site properties is needed to manage soils in accordance with their potential properties. Numerous attempts to predict the strength of the soils were made; however, all are based on static loading experiments, which assume that equilibrium in settlement for stepwise increasing loads is achieved. This approach neglects the dynamic nature of soil loading processes during field traffic where loads are applied mostly short term and where multiple loading events may cumulatively add to the total compression. Thus, the increase in irreversible deformation of


FIGURE 3.1 Summary of the effects of stress application on soil properties and functions. (Translated and slightly modified from van der Ploeg, R.R., W. Ehlers, and R. Horn. 2006. Schwerlast auf dem Acker. Spektrum der Wissenschaft August, 80–88. ISSN: 0170-2971.)

arable soil by agricultural machinery can not only be related to the increasing mass of machines (defined as static approach) but also enhanced by the increase of wheeling frequency as a dynamic component. The relevance of wheeling frequency can be estimated based on the calculations of Olfe (1995). Considering an average-sized wheat-production farm, the number of load repetitions in a time period of 5 years may add up to 50 events for 85% of the field and up to 100 events for permanent wheeling tracks.

An additional threat concerning soil degradation is caused by tillage erosion as the actual soil loss can exceed by far 20 Mg ha^{-1} and per tillage operation. This effect is the more pronounced, the drier the soil, the weaker the aggregates, the higher the dynamic energy input by agricultural machinery, and the greater the field size (Karlen, 2004; Reicosky et al., 2005; da Silva et al., 2006; Van Oost et al., 2006). The kinetic energy applied during seedbed preparation under dry conditions alone already results in an increased mass transport by wind. Additionally, the unproductive water loss due to evaporation from an increased accessible pore and particle surface and the enhanced organic-matter decomposition due to tillage both contribute to global change problems (Lal, 2005). Soil creep, mudflow after rainstorms, and intensified surface-water runoff are due to reduced/prevented vertical water infiltration in soils generating pronounced lateral fluxes of water, solids, and nutrients. The loss of shear strength, defined by the angle of internal friction and cohesion, of near-saturated soils subject to buoyancy forces that cause such lateral fluxes produces tremendous damage to the landscape and human beings. Related economic impacts are estimated to exceed billions of euros worldwide (van den Akker et al., 1998). In addition

to productivity losses of soils in farming regions, the loss in biodiversity and the effects on global changes by modifying physicochemical processes result in the emission of greenhouse gases and the mobilization of heavy metals in soils due to redox reactions, which in turn cause groundwater pollution threats.

If, on the other hand, the tilled soil dries out, transport by wind may occur, resulting in severe reductions in potential site productivity. Furthermore, the preparation of a seedbed leads to abrupt changes in the transport of gas, water, ions, and heat between the tilled and deeper soil layers (Boone and Veen, 1994; Ball et al., 2000; Lipiec and Hatano, 2003). This is especially true concerning preferential flow through structured soils (Hendrickx and Flury, 2001). When it comes to the quantification of soil deformation with respect to the induced changes of physical functions, again the dynamic nature of soil loading processes during field traffic must be considered, where loads are applied mostly short term and where multiple loading events may cumulatively add to the total compression, although the statically determined precompression stresses are not exceeded and should result in no further compression.

Such anthropogenic changes make clear that the discussion of soil process dynamics within the soil profile is most relevant. Some of the interactions between soil structure, water status, and aeration of structured soils in relation to root growth and compressibility of arable land have been described by Emerson et al. (1978). In current discussions on sustainability, soil compaction is repeatedly mentioned as one of the main threats to agriculture, which should be avoided (Soane and van Ouwerkerk, 1994; Pagliai and Jones, 2002; Horn et al., 2006; Toth et al., 2008).

The aim of this chapter is to analyze the relationships between stress, strain, and strength as well as the consequences of soil deformation for physical and physicochemical properties. It also includes a description of well-established and new methods for measuring mechanical properties of soils and introduces possibilities for modeling soil strength and stress–strain relationships from the micro- to the macroscale.

3.2 Stress–Strain Relationships in Soils

3.2.1 Stress Theory

3.2.1.1 Definitions

Before discussing the methods of field and laboratory stress measurement as well as factors influencing compaction, one needs to differentiate between several terms used to define compressive properties. These definitions have been taken from Fredlund and Rahardjo (1993), Hartge and Horn (1999), Parry (2004), and McCarthy (2007).

3.2.1.2 Mechanical Stresses

Stress is defined as force per area within a solid body. Stress can be induced by external or internal forces, which lead, if the body is nonrigid, to a change in the body's volume and/or shape expressed as deformations or strains. The mechanical behavior of a soil can therefore be characterized by its stress–strain relationships.

Strength is typically referred to as the maximum amount of stress a solid material can withstand before it fails; thus, exceeding soil strength results in soil failure or yield. Strength depends on internal parameters such as particle-size distribution, type of clay minerals, nature and amount of adsorbed cations, content and type of organic matter, aggregation induced by swelling and shrinkage, stabilization by roots and humic substances, bulk density, pore-size distribution and pore continuity of the bulk soil and single aggregates, water content, and/or matric potential (Horn, 1981).

3.2.1.2.1 Stress State

The number of stress state variables required to define the stress state depends primarily upon the number of phases involved. The effective stress σ' can be defined as a stress variable for saturated conditions (Terzaghi, 1936) and is the difference between the total stress (σ) and the neutral stress (u_w), which is equal to the pore water pressure:

$$\sigma' = \sigma - u_w, \tag{3.1}$$

where
σ' is transmitted by the solid phase
u_w is transmitted by the liquid phase, respectively

In unsaturated soil, stresses are transmitted by the solid, liquid, and gaseous phases. Thus, Equation 3.1 becomes (Bishop, 1959)

$$\sigma' = (\sigma - u_a) + \chi(u_a - u_w), \tag{3.2}$$

where
u_a and u_w are pore air and water pressures, respectively
χ is a factor that is often assumed to be directly related to the degree of saturation (S_r)

At saturation ($u_w = 0$ kPa), $\chi = 1$, while at $u_w = -10^6$ kPa, $\chi = 0$.

For sandy, less compressible, and nonaggregated soils, χ can be estimated as

$$\chi = 0.22 + 0.78 S_r. \tag{3.3}$$

For silty and clayey soils, the values of the parameters in Equations 3.1 and 3.2 depend on soil aggregation, pore arrangement and strength, and hydraulic properties. Thus, the material function of the components in structured soils is only valid as long as the internal soil strength is not exceeded by the externally applied stresses. It changes if, for example, aggregates are destroyed during soil deformation and the structural properties reduce to those that depend merely on texture.

The extent of soil deformation can be described by stress–strain relationships and by their relative proportions. In the absence of gravitational and other applied forces, effective stresses in three-phase soil systems can be expressed as a tensor containing three normal stresses and six shearing components; assuming symmetry of the stress tensor, the shear stresses are reduced to three independent components. Therefore, three normal stress (σ_x, σ_y, σ_z) and three shear stress (τ_{xy}, τ_{xz}, τ_{yz}) components must be determined to fully define the stress state at every location in a solid body (Nichols et al., 1987; Horn et al., 1992). For an unsaturated soil, the stress state can be described completely by a symmetric matrix, which can be written as two independent stress tensors (Fredlund and Rahardjo, 1993):

$$\begin{bmatrix} \sigma_x - u_a & \tau_{yx} & \tau_{zx} \\ \tau_{xy} & \sigma_y - u_a & \tau_{zy} \\ \tau_{xz} & \tau_{yz} & \sigma_z - u_a \end{bmatrix} \tag{3.4}$$

and

$$\begin{bmatrix} (u_a - u_w) & 0 & 0 \\ 0 & (u_a - u_w) & 0 \\ 0 & 0 & (u_a - u_w) \end{bmatrix}. \tag{3.5}$$

A graphical representation of the stress state variables and the action of water menisci at intergranular contacts in an unsaturated soil is provided in Figure 3.2.

For symmetric tensors, it is always possible to find a coordinate system in which the shear components become 0 and the tensor becomes diagonal. In this principal axis system and assuming that the pore air pressure u_a = atmospheric pressure, the stress tensor in Equation 3.4 simplifies to

$$\begin{bmatrix} \sigma_1 & 0 & 0 \\ 0 & \sigma_2 & 0 \\ 0 & 0 & \sigma_3 \end{bmatrix} \tag{3.6}$$
FIGURE 3.2 (a) Stress state variables for an unsaturated soil. (b) Schematic sketch of water menisci at interparticle/interaggregate contacts illustrating the effect of pore water pressure (u_w) on intergranular tension stresses. (Supplemented after Fredlund, D.G., and H. Rahardjo. 1993. Soil mechanics for unsaturated soils. John Wiley & Sons, New York.)

with principal stresses σ_1, σ_2, and σ_3 acting on the solid. For a single-valued characterization of the stress state, two invariants of the stress matrix are often used—the mean normal stress (MNS) and the octahedral shear stress (OCTSS; Koolen, 1994):

$$MNS = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3), \qquad (3.7)$$

$$OCTSS = \frac{1}{3}\sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2}. \qquad (3.8)$$

3.2.1.2.2 Stress Propagation

Each applied force per contact area is transmitted into the soil in three dimensions and can alter the physical, chemical, and biological properties of the soil (e.g., water infiltration, rootability) if the internal mechanical strength is exceeded. Stress propagation theories are rather old and have been often modified and adapted to in situ situations. The fundamental theory of Boussinesq (1885) is only valid for completely elastic material, while Fröhlich (1934) and Soehne (1958) included elastoplastic properties through the introduction of concentration factor values (υ_k). More comprehensive descriptions of these models are given by Koolen and Kuipers (1983), Bailey et al. (1986), Johnson and Bailey (1990), and Bailey et al. (1992). Horn et al. (1989) introduced precompression stress (P_v)-dependent values for the concentration factor, which are smaller in the recompression stress range, while they increase in the virgin compression stress range. The latter can be explained by the plastic deformation behavior, which causes a deeper stress transmission closer to the perpendicular line.

3.2.1.3 Hydraulic Stresses

The effective stress (Equation 3.1) defines the forces per given area, which can stabilize the soil particles against any kind of soil deformation. The hydraulic stress component (u_w) can either be negative (concave water menisci) or positive (convex water menisci). In case of convex menisci, it can result in weakening of the total soil system, especially when shear forces are applied. In case of pure compression under saturated conditions, however, effective and hence compressive stresses are reduced while the neutral stress (water pressure) bears part or even the entire externally applied load. In most cases, air pressure (u_a) in Equation 3.2 is ignored, assuming that gas pressure in soil during loading is in equilibrium with atmospheric conditions.

If, on the other hand, hydraulic stresses become negative (=suction), the contractive forces even increase the effective stress (Figure 3.2). In addition to capillary forces associated with water, salt effects (i.e., water potential = sum of matric and osmotic potential) and hydrophobic substances can also increase soil strength by altering wetting angle, cohesion, internal friction, as well as elastic and viscous properties of the soil (Barré and Hallett, 2009; Markgraf and Horn, in press).

Hydraulic stresses result in shrinkage in almost all soils. In an initially homogenized state, soils undergo proportional and thereafter residual shrinkage during the first drying phase. Depending on the history of the formerly applied hydraulic and mechanical stresses, the shrinkage curve pattern, however, shifts and it must be now differentiated between structural shrinkage (=structural rigidity), virgin, and residual shrinkage behavior (Groenevelt and Grant, 2001; Braudeau et al., 2004; Peng and Horn, 2005). Structural shrinkage defines the internal soil strength caused by deformation related to capillary forces. Structural shrinkage is more pronounced, the more often and intensive soil dries out. Horn (1994a), for example, described the effect of the drying frequency and intensity on shrinkage behavior and pointed out that soil strength increases the more often and longer contracting water menisci occur while only a few but

very intense drying processes are mostly not capable of rearranging particles to form a rigid structure with smaller entropy (Horn and Dexter, 1989).

The power of capillary forces and their strengthening potential for soil architectures can be demonstrated by a simple computation. Given the mass of the earth (~6×10^{24} kg) and the area of, for example, Germany (~$360,000 \, km^2$) of which 50% is arable soil (=$180,000 \, km^2$) and assuming a thickness of the plowed topsoil of 30 cm with a hypothetical specific surface area of $800 \, m^2 \, g^{-1}$ (for simplicity we assume the soil to consist of smectitic clay and 2%–4% of organic carbon), we would end up with a total surface area of ca. $6.5 \times 10^{19} \, m^2$. If we furthermore presume that water menisci at a potential of pF 4 would be effective over the total surface ($\chi \rightarrow 1$, assuming a very high negative air-entry pressure), then the sum of menisci forces acting within the topmost 30 cm of arable soils in Germany could carry the total mass of the earth.

3.2.1.4 Stress Coupling

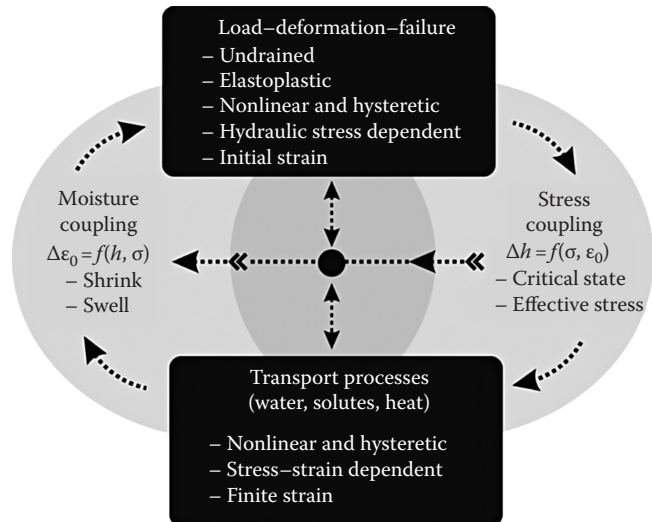
Based on the findings by Baumgartl (2003), who described the similarity of mechanical stress–strain curves and shrinkage curves resulting from hydraulic stresses (Figure 3.3), Peng and Horn (2008) proved that the link between mechanical and hydraulic "pre"stresses results in nearly identical changes in shrinkage curves. Additionally, Baumgartl (2003) explained the differences between mechanically induced collapse and matric potential-dependent shrinkage patterns by the dimensionless χ factor, which, however, is difficult to determine experimentally. Accounting for the interactions between mechanical and hydraulic processes is very important to understand the deformation behavior of unsaturated soils. Nevertheless, their description is inherently complex involving effective stress theory, loading rate dependency, and nonlinear hysteretic coupled transport and stress–strain functions.
FIGURE 3.3 Stress–strain relationships showing the similarity between compaction (right ordinate) and shrinkage curves (left ordinate). (Modified from Baumgartl, T. 2003. Koppelung von mechanischen und hydraulischen Bodenzustandsfunktionen zur Bestimmung und Modellierung von Zugspannungen und Volumenänderungen in porösen Medien. Habilitation Thesis. Schriftenreihe Inst. Pflanzenernaehrung und Bodenkunde, Germany, No. 62, 133 pp. ISSN: 0933-680X.)


FIGURE 3.4 Conceptual framework for modeling coupled soil mechanical and hydraulic processes. The *stress-coupling* routine models pore water pressure changes (Δh) as a function of stress (σ) or strain (ε_0). The *moisture-coupling* routine models strain changes ($\Delta \varepsilon_0$) as a function of pore water pressure (h) and effective stress (σ'). (From Richards, B.G., and S. Peth. 2009. Modelling soil physical behaviour with particular reference to soil science. Soil Till. Res. 102:216–224.)

According to Richards and Peth (2009), mechanical and hydraulic processes can be coupled by treating the initially independent load-deformation and transport processes by an incremental approach as shown in Figure 3.4. This coupling is most important in modeling the interaction between water flow and deformation/failure as, for example, encountered in swelling soils, landslides on slopes during rainstorms, and consolidation of high water content soils. In a stress-coupling routine, changes in pore water pressure (h) are calculated as a function of changes in stress (σ) or strain (ε), and in a moisture-coupling routine, changes in stress or strain are calculated as a result of pore water pressure changes related to both water transport and load deformation. A detailed mathematical description of the finite element model (FEM) used for mechanical and hydraulic stress coupling and the underlying constitutive relations and material parameters is given in Richards and Peth (2009).

3.2.1.5 Soil Strength Changes due to Stress-Dependent Effects on Hydraulic Properties

Total stress application affects interparticle bonding as well as pore-size distribution, pore geometry, and the degree of saturation, which either weakens the soil during compression or makes it even stronger. While the former is caused by soil settlement, reducing pore volume and hence increasing the degree of saturation, the latter is related to the stress-dependent water redistribution in newly formed finer pores at the expense of bigger and already air-filled ones causing more negative matric potential values, thus increasing effective stresses (Equation 3.2). Fazekas and Horn (2005) describe the effect of static loading on the transition between stress-induced soil strengthening and weakening and found that this change occurs close to the precompression

stress value. The changes resulted initially in a strength increase and the pore water pressure became more negative, while at higher stresses the pore water pressure even reached positive values starting from −30 kPa initial matric potential. If external forces are applied as repeated short-time loading (e.g., due to wheeling or trampling) or if shear deformation-induced rearrangement of particles occurs, we also have to consider the "water menisci pumping effect due to short-term suction changes" because it enhances the weakening process due to a more pronounced and more complete swelling, finally resulting in a complete soil homogenization (Horn, 1976, 2003; Pietola et al., 2005; Krümmelbein et al., 2008). Janssen (2008) measured stress-induced changes in pore water pressure in paddy soil samples. Increasing frequency of loading and unloading changed water menisci forces from negative to positive pore water pressure values and caused complete soil softening. Similar effects were also reported for short-term cyclic loading of homogenized soil, where even when the soil was unsaturated at an initial matric potential of −6 kPa, positive pore water pressure was measured during the short-term loading phases (Peth and Horn, 2006b). Water-induced soil softening is also evident when shear forces are applied to the soil surface, for example, by wheeling due to slip effects (Horn, 2000; Horn et al., 2006). Horn et al. (1995) proved the effect of shear-induced changes in pore water pressure in comparison with the previously applied static stress (Figure 3.5). Even if the consolidated stress–strain state had been

reached due to a given static loading, the following so-called consolidated shear process again caused an additional compaction and an extra change in the pore water pressure values. The more rapid the shear process occurs and the smaller the hydraulic conductivity even at increased hydraulic gradients, the more positive become the pore water pressure values and the weaker the total soil (Hartge and Horn, 1999).

3.2.2 Strain Theory

Mechanical processes in soil are generally stress dependent. All stresses exceeding the internal soil strength result in failure, which can be defined either by an irreversible plastic volume decrease (=soil compaction) or by a rearrangement of soil particles at a constant bulk soil volume (=shearing). Analogous to stress, strain can be described by normal (ε_x, ε_y, ε_z) and shear strain (ε_{xy}, ε_{xz}, ε_{yz}) components, which are also described completely by a symmetric strain tensor:

$$
\begin{bmatrix}
\varepsilon_x & \varepsilon_{xy} & \varepsilon_{xz} \\
\varepsilon_{xy} & \varepsilon_y & \varepsilon_{yz} \\
\varepsilon_{xz} & \varepsilon_{yz} & \varepsilon_z
\end{bmatrix}. \tag{3.9}
$$

In the corresponding principal axis system, the strain tensor reduces to

$$
\begin{bmatrix}
\varepsilon_1 & 0 & 0 \\
0 & \varepsilon_2 & 0 \\
0 & 0 & \varepsilon_3
\end{bmatrix}. \tag{3.10}
$$

The volumetric strain (ε_{vol}) can be calculated as

$$
\varepsilon_{vol} = \varepsilon_1 + \varepsilon_2 + \varepsilon_3 = \varepsilon_x + \varepsilon_y + \varepsilon_z. \tag{3.11}
$$

Note that the tensor trace is invariant under coordinate transformations. Furthermore, the strain components and their proportions depend on internal and external parameters and require the determination of all components in a 3D volume.

3.2.2.1 Volumetric Deformation

Compression refers to a process that describes the increase in soil mass per unit volume (increase in bulk density) under an externally applied load or under changes in internal pore water pressure. Considering the soil as a continuum, soil movement can be described as a translation field (*d*) whose local properties are usually characterized by three components of its spatial derivative:

FIGURE 3.5 Changes in shear stress, sample height, and pore water pressure during shearing. The samples were predried to −6 kPa and preconsolidated prior shearing. Upon shearing at the same applied stress, the sample further consolidated (height change) and pore water pressure increased reaching even positive values during shearing. After normal and shear stress were removed, pore water pressure decreased to a final value more negative than the initial pore water pressure. (From Horn, R., T. Baumgartl, R. Kayser, and S. Baasch. 1995. Effect of aggregate strength on changes in strength and stress distribution in structured bulk soils, p. 31–52. *In* K.H. Hartge and R. Stewart (eds.) Soil structure: Its development and function. CRC Press, Boca Raton, FL.)

$$
\nabla \cdot \vec{d} =
\begin{bmatrix}
\dfrac{\partial}{\partial x} d_x & \dfrac{\partial}{\partial x} d_y & \dfrac{\partial}{\partial x} d_z \\[2ex]
\dfrac{\partial}{\partial y} d_x & \dfrac{\partial}{\partial y} d_y & \dfrac{\partial}{\partial y} d_z \\[2ex]
\dfrac{\partial}{\partial z} d_x & \dfrac{\partial}{\partial z} d_y & \dfrac{\partial}{\partial z} d_z
\end{bmatrix}. \tag{3.12}
$$

Every change in stress state therefore results in soil deformation. This divergence (volumetric strain) can be expressed as the divergence of the deformation field:

$$\varepsilon_{vol} = \mathrm{div}(\vec{d}) = \nabla \cdot \vec{d} = \mathrm{tr}(\nabla \cdot \vec{d}) = \frac{\partial}{\partial x}d_x + \frac{\partial}{\partial y}d_y + \frac{\partial}{\partial z}d_z, \quad (3.13)$$

and results in volumetric compression or extension. The terms of the right-hand side of Equation 3.13 show the corresponding strains in *x*, *y*, and *z* directions and how they are related to respective deformation components.

3.2.2.2 Shear Deformation

Shearing a soil volume always leads to a pronounced volume constant rearrangement of particles often resulting in significant changes in pore functions by decreasing pore connectivity or continuity and changes in interparticle strength due to a loss of cohesion (Figure 3.6). The stress/strain at which the interparticle strength is lost and the soil begins to fail is referred to as yield stress/strain. The resistance of a soil toward shear deformation is described by shear moduli (*G*), which will be explained in more detail in Section 3.3 (*rheometrical parameters*).

3.2.3 Stress–Strain Processes

Generally, mechanical processes in soils are described by the stress/strain equation:

$$\begin{bmatrix} \sigma_x(\vec{x},t) & \tau_{xy}(\vec{x},t) & \tau_{xz}(\vec{x},t) \\ \tau_{xy}(\vec{x},t) & \sigma_y(\vec{x},t) & \tau_{yz}(\vec{x},t) \\ \tau_{xz}(\vec{x},t) & \tau_{yz}(\vec{x},t) & \sigma_z(\vec{x},t) \end{bmatrix}$$
$$= f \begin{bmatrix} \varepsilon_x(\vec{x},t) & \varepsilon_{xy}(\vec{x},t) & \varepsilon_{xz}(\vec{x},t) \\ \varepsilon_{xy}(\vec{x},t) & \varepsilon_y(\vec{x},t) & \varepsilon_{yz}(\vec{x},t) \\ \varepsilon_{xz}(\vec{x},t) & \varepsilon_{yz}(\vec{x},t) & \varepsilon_z(\vec{x},t) \end{bmatrix}, \quad (3.14)$$

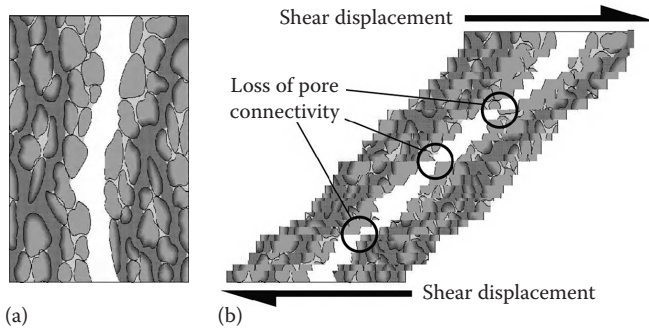
(a)　　(b)


FIGURE 3.6 Schematic sketch of the effect of shear displacement on pore continuity (b) in comparison with an "unstressed" pore system (a).

where *f* defines the soil-specific material properties. In the case of a linear elastic isotropic material, the tensor notation reads as follows:

$$\begin{bmatrix} \sigma_x & \tau_{xy} & \tau_{xz} \\ \tau_{xy} & \sigma_y & \tau_{yz} \\ \tau_{xz} & \tau_{yz} & \sigma_z \end{bmatrix} = \frac{E}{1+v}\begin{bmatrix} \varepsilon_x - \varepsilon_m & \varepsilon_{xy} & \varepsilon_{xz} \\ \varepsilon_{xy} & \varepsilon_y - \varepsilon_m & \varepsilon_{yz} \\ \varepsilon_{xz} & \varepsilon_{yz} & \varepsilon_z - \varepsilon_m \end{bmatrix}$$
$$+ \frac{E}{3(1-2v)}\begin{bmatrix} \varepsilon_m & 0 & 0 \\ 0 & \varepsilon_m & 0 \\ 0 & 0 & \varepsilon_m \end{bmatrix} \quad (3.15)$$

where

　$E = \Delta\sigma/\Delta\varepsilon$ (Young's modulus or modulus of elasticity)
　v is the Poisson's ratio

The first tensor on the right-hand side of Equation 3.15 describes the volume constant shear deformation and the second tensor the volumetric strain with the mean volume strain ε_m defined as

$$\varepsilon_m = \frac{1}{3}(\varepsilon_x + \varepsilon_y + \varepsilon_z) = \frac{1}{3}\varepsilon_{vol}. \quad (3.16)$$

Further details on the notions of stress–strain relationships can be found in Fredlund and Rahardjo (1993) and Warrick (2002).

To describe nonlinear elastic–plastic soil behavior as a function of stress, soil–water suction, and stress history, Richards (1978) introduced, based on the analysis of experimental data, a constitutive model, where the mechanical material properties are defined as hyperbolic functions allowing to treat soil as nonlinear and irreversible hysteretic material. The stress-dependent mechanical material properties are defined based on standard soil mechanical material parameters (bulk modulus, shear modulus, and Mohr–Coulomb failure criteria), which can be readily derived from soil tests (e.g., consolidation test, shear test, triaxial test; Section 3.3.4). Bulk modulus *K* and shear modulus *G* characterize the stiffness and shear strength of the soil, respectively. The basic relationships for the two simple stress-dependent moduli are (Richards and Peth, 2009)

$$K = k_1\sigma_m^n + k_2h^m + k_0 \quad (3.17)$$

and

$$G = (g_1\sigma_m^p + g_2h^r)\left(1 - \left(\frac{\tau}{\tau_f}\right)^q\right) + g_0, \quad (3.18)$$

where

　σ_m is the previous maximum of the mean normal stress $((\sigma_1 + \sigma_2 + \sigma_3)/3)$
　h is the soil water suction
　τ is the shear stress
　τ_f is the yield stress according to the employed yield criteria

The shape of the material functions is further defined by empirical material constants k_{0-2}, g_{0-2}, n, m, p, r, and q, which are

derived directly from fitting soil test data or by back-analyzing soil test results with an FEM approach (for further details see Section 3.7.3 and Richards and Peth (2009)).

3.3 Soil Strength–Stability Indicators and Their Measurement

Soil strength and elasticity are mechanical key determinants for maintaining efficient functionality and ultimately quality of soils. Indicators describing and quantifying the mechanical resistance, deformation, and resilience of agricultural soils are important for several reasons. One is to assess if external mechanical loads applied to soils during field operations modify solid–void architectures and volume relationships through particle relocations and how far this may detrimentally affect pore functions. Another is to evaluate the penetrability of soil horizons and aggregates by roots and soil organisms while prospecting soils for water, nutrients, and food. A third reason is to estimate the risk for soil mass movements and soil erosion processes along slopes.

Soil scientists and civil engineers are likewise interested in measuring soil mechanical stability parameters, although with sometimes contrasting goals. In fact, many of the mechanical parameters that are commonly used in agricultural soil science originated in the field of civil engineering. On the other hand, civil engineers have adapted methods from agricultural soil science (e.g., Atterberg's limits) and nowadays realize the importance of understanding soils as bioactive media where interacting physical and biological processes in turn have a strong influence on soil strength. However, recognizing soils as deformable (elastoplastic) multiphase systems with an internal structure, we need to define boundary-dependent strength/stability limits in order to estimate and ultimately predict deformation-induced changes in physical, chemical, and biological soil functions.

Most commonly used and well-established parameters characterizing the mechanical strength/stability of soils on multiple scales ranging from interparticle to pedon levels will be described in the following, including methods for their determination. Where appropriate, we supplemented this section with new techniques and methodologies in the field of soil mechanical research.

3.3.1 Soil Consistency

The consistency of soils is a result of cohesive and adhesive forces acting between particles and between fluid-phase molecules and the solid surface, respectively. Together, they determine the interparticulate resistance to deformation, rupture, and flow. Soil wetness obviously has a strong influence on the kind of reaction against external forces (e.g., hard, friable, soft, plastic, sticky, and viscous). Atterberg (1911) has defined different classes of soil behavior based on soil wetness, which is a simple yet useful method to judge soil consistency and hence workability. The so-called *Atterberg's limits* quantify the soil's resistance to mechanical energy as a function of gravimetric water content (Θ_g):

3.3.1.1 Liquid Limit

The liquid limit is determined with a CASAGRANDE apparatus (Casagrande, 1932) where a homogenized moist sample is placed in a special bowl and a V-shaped trench is cut from the top to the bottom (Kézdi, 1974). The bowl with the sample is bounced up and down by a special crank onto a hard rubber block at a frequency of two strokes per second until the trench is closed at a length of <1 cm. The number of strokes when this condition is met is counted and the gravimetric water content determined on a subsample at the end of the test. The liquid limit is defined as the water content (Θ_g) where the test criteria are fulfilled at 25 strokes corresponding to a certain "standardized" amount of energy applied to the soil. The test is repeated for at least four water content values and the number of strokes plotted versus the water content on a semilogarithmic paper, finally producing a linear line. The liquid limit increases with clay and organic-matter contents, ionic strength, cation valency, and proportion of 2:1 type clay minerals in the soil.

3.3.1.2 Plastic Limit

The plastic limit is defined as the water content (Θ_g) when homogenized soil samples begin to crack and crumble when rolled to a diameter <3 mm. It has practical implication in civil engineering and agriculture since it determines the lower critical water content at which soils become plastic and hence difficult to till or excavate.

3.3.1.3 Plasticity Index

The difference between the water contents (Θ_g) at the liquid limit (LL) and plastic limit (PL) is the so-called plasticity index (PI = LL – PL), which is often used as an indicator for soil workability. With an increasing plasticity index, soils become more sensitive to plastic deformation. The higher the plasticity index the smaller is the water-content range at which soils can be tilled efficiently and trafficked without considerable soil deformation. The smaller is also the angle of internal friction over a wider range of water contents. Many attempts have been made to correlate PI to soil strength (Kézdi, 1974; Hartge and Horn, 1992; Kretschmer, 1997). In principle, this test only gives information on minimum strength values correlated with soil water content. It is furthermore limited to silty, loamy, and clayey soil samples while such correlation fails and is too insensitive for sandy material. Thus, especially coarse-textured soils cannot be classified by these data.

3.3.1.4 Rheometrical Parameters

Advances in rheological research as an independent science have brought sophisticated techniques for quantifying flow behavior and deformation properties of viscoelastic substances (mainly fluids)—the most important parameters are shear modulus (G), plastic viscosity (η_p), and yield stress (τ_y).

Although first rotational viscometers (1888) and later rheometers (~1951) have been developed, early modern microprocessor-based systems, which are available since the 1980s, added more

options for rheological testing including creep, relaxation, and oscillation tests. The methods are today well established and widely used in polymer, chemical, and material sciences as well as in the paper and food industries.

Despite its potential applicability, however, they are still not commonly employed in soil science research. One of the earliest contributions has been made though by Yasutomi and Sudo (1967) who used a low-frequency forced oscillation viscometer to study viscoelastic properties of soil. Later, Keren (1988) and Hesterberg and Page (1993) used a viscometer to investigate the influence of electrolyte composition and pH on rheological characteristics of clay mineral suspensions. Studies based on mineral suspensions certainly aid the understanding of the principle influence of surface chemistry on mechanical solid–interface interactions but have the drawback of ignoring the pertinent action of water as a lubricant during deformation processes. More recently, Ghezzehei and Or (2001) have used a rotational rheometer with a parallel-plate sensor system to determine these *rheometrical parameters* on natural soils and clay samples under more realistic field-moisture conditions. Higher water contents and high stress amplitudes resulted in lower viscosity of all investigated soils. Although this is not surprising, the authors could demonstrate that rheometry is a suitable and sensitive technique that enables us to quantify rheological properties of soils based on physically well-defined boundary conditions. Also Markgraf et al. (2006) investigated rheological characteristics of natural soil samples (Avdat loess, smectitic vertisol, and kaolinitic oxisol) using a parallel-plate rheometer. By conducting so-called amplitude sweep tests (oscillatory test with continuously increasing deformation), they were able to reveal differences in structural stabilities between the smectitic vertisol and the kaolinitic oxisol and the influence of electrolyte concentrations on rheological parameters of Avdat loess samples.

It would go beyond the scope of this chapter to describe the principles of rheometry in great detail. We therefore will only outline the basic test and analysis procedures in the following. Readers that are more interested in this technique will find useful staring points in Ghezzehei and Or (2001), Markgraf et al. (2006), and Mezger (2006).

The sample (usually a remolded paste at defined water content) is placed between two parallel plates (diameter 2.5 cm) with an adjustable gap size commonly between 2 and 4 mm (Figure 3.7). To set up the test, the upper plate is slightly pressed against the sample to ensure contact and time is given for stress dissipation. To avoid slip at the interface between the sample and the plates, both the upper and lower plates are furrowed. In an amplitude sweep test, the upper plate rotates (oscillatory) at a predefined frequency (e.g., 0.5 Hz) and variable amplitude beginning with very small shear deformations (corresponding to angular deflection) up to the maximum shear deformation where the angular deflection is equal to the gap spacing between the plates (e.g., 4 mm deflection at a gap spacing of 4 mm). Shear strain γ is expressed as percentage ranging from 0% (no deflection) to 100% (maximum deflection).

(a)

(b)
FIGURE 3.7 Rheometer with a parallel-plate measurement system. A remolded soil paste is placed between two furrowed plates by moving down the upper rotational shaft. (a) The upper plate rotates (arrows indicate the rotation in an oscillatory test) while the lower plate remains static. During oscillation, shear force (torque) and angular velocity are measured by sensors placed in the shaft of the upper plate. (b) Shows the sample after the test. A typical result of a rheometrical test is shown in Figure 3.8.

A typical rheological parameter calculated from an amplitude sweep test is the shear modulus $G = \tau/\gamma$, where τ is the shear stress and γ the shear strain. The shear modulus is distinguished into a storage modulus $G' = \tau_A/\gamma_A \cos \delta$ and a loss modulus $G'' = \tau_A/\gamma_A \sin \delta$ representing the elastic and viscous part of deformation, respectively (Figure 3.8). The subscript A denotes the amplitude of the deflection that corresponds to the shear stress and shear deformation pair. The phase shift angle δ describes the viscous reaction of the sample to the prescribed shear deformation or shear stress. At $\delta = 0°$ (tan $\delta = 0$), the sample deforms ideal elastic (system response is instantaneous, that is, stress is proportional to strain); at $\delta = 90°$ (tan $\delta = \infty$), the sample shows ideal viscous behavior (system response is shifted by 1/4th of a full oscillation). In other words, the higher the phase shift angle δ the higher is the viscous and the lower is the elastic part of deformation, respectively. Hence, at small tan δ values, the storage modulus G' exceeds the loss modulus G'' and vice versa for tan δ values >1. The magnitude of G' or G'' in turn represents the resistance of the sample against deformation irrespective of whether it is elastic or viscous. However, at tan $\delta = 1$, the yield point is reached indicating that the sample reacts predominantly viscous. For shear deformation exceeding the yield point, the sample becomes quickly more viscous (Figure 3.8). Tan δ is also referred to as loss factor since it indicates the fraction of mechanical energy introduced into
FIGURE 3.8 Schematic diagram showing a typical result of a rheo-metrical test. G' = storage modulus (Pa) and G'' = loss modulus (Pa) correspond to the elastic and viscous deformation, respectively. Tan δ indicates the viscoelasticity of the sample: for tan δ = 0, deformation is ideal elastic; for tan δ = ∞, deformation is ideal viscous; for tan δ = 1 (yield point), deformation is equally viscous and elastic. Note that both moduli (G' and G'') and strain are plotted on log scale.

the system that is lost in deformation. Note that possibilities for variations in boundary conditions during rheometer tests (stress or strain controlled, different stress–strain paths, stress relaxation, oscillation frequency) are numerous and choice of either methodology depends on the material under investigation. For soils, however, amplitude sweep tests have produced interpretable results and seem to be sensitive for a wide range of soil conditions (salt effects, water effects, and organic-matter effects) and allow expressed as yield stress a quantification of micromechanical soil strength (Markgraf et al., 2006; Markgraf and Horn, 2007).

3.3.2 Bulk and Proctor Density

Bulk density is defined as mass per unit volume ignoring the internal arrangement of solids and voids, which limits its use to interpret strength properties and functions of structured soils. For example, two soils at the same bulk density, one aggregated and the other not, can have significantly different strengths. Employing bulk density for deriving site-specific soil properties should therefore in general be done with care (Horn and Kutilek, 2009).

Nevertheless, as far as remolded or freshly deposited soil material is concerned, bulk density may be a suitable indicator for the degree of compaction of such soils. Especially, in civil engineering, often the state of maximum compaction of a given material is of interest and the water content where compactibility of a soil material is at optimum, that is, where least energy

input results in maximum effect (=maximum density). To evaluate the soil moisture condition where compaction of homogenized soil samples is most efficient, *Proctor tests* are commonly employed (Proctor, 1933). Here, a remolded soil at various water contents (Θ_g) is filled into a container and compacted by dropping a weight (~2.5 kg) on the soil from a height of ~30 cm and for a defined number of strokes (usually 25). A series of tests are performed at different water contents and the resulting bulk density measured after each test. Bulk densities and corresponding water contents (Θ_g) are plotted on a graph, which represents the so-called *Proctor curve*. The water content where the compaction reaches a maximum is called the optimum water content (Θ_{opt}) and the maximum density is referred to as *Proctor density* (ρ_p). The coarser the soil sample, the higher ρ_p and the smaller Θ_{opt}. For example, sandy soils have higher ρ_p values than silty or clayey soils, while the latter require a higher water content (Θ_{opt}) to reach the optimum bulk density. Further, the more heterogeneous the grain-size distribution, the higher are ρ_p and Θ_{opt}. Strongly aggregated soils behave like coarser soil materials, that is, also here the proctor density is higher and the corresponding optimal water content lower than in less-aggregated soils. If aggregates themselves are destroyed during the test, ρ_p gets smaller while Θ_{opt} increases compared with completely homogenized material.

3.3.3 Penetration Resistance

Soil resistance to any kind of deformation is determined by various types of penetrometers. The most simple is a thin metal rod (<0.5 cm diameter) with a defined tip shape. Frequently, the tip angle is 30° to simulate root properties or earthworm shapes. The penetrometer can be either pushed into the ground by the constant weight of a falling hammer or it can be driven by a motor at constant speed. The output readings can be either penetration depth per hammer stroke or depth stress depletions, which have to be overcome by the penetrating body in more sophisticated models. Penetration resistance is correlated with root growth, earthworm activity, and tillage effects. When penetration resistance exceeds 2 MPa, root growth is often reduced by half, while values >3 MPa often prevent root growth. Tillage may increase the critical stress value of a hardpan to >3.5 MPa depending on the nature of the pore system and the type of soil structure. Because the penetrometer needle is not as flexible as a root, which can choose planes of weakness for growth, penetrometer readings quantify resistances mainly in the vertical direction. In addition, the penetrometer readings only integrate impeding effects and cannot identify its causes. Despite a voluminous literature on the effect of increasing bulk density and water content on penetration resistance, extrapolation to land management situations is limited. Penetrometer readings can be used to create maps of derived properties (e.g., definition of sites with a given strength irrespective of its origin). Such data can be interpreted using statistical variograms, fractal analyses, or simply by stating that values are spatially different.

3.3.4 Precompression Stress and Compressibility Indices

The compression of a soil means a change not only in total pore volume but is generally accompanied by a change in pore-size distribution including related soil functions (e.g., permeability, storage of water, aeration, gas exchange, heat diffusivity). Hence, the determination of the soil's resistance to compaction and the magnitude of volume changes in soils exposed to external mechanical stresses are of paramount importance for preserving soil physical quality. A number of laboratory tests under precisely defined boundary conditions may be used to quantify soil strength and volume change behavior of soils (Table 3.1).

3.3.4.1 Uniaxial Compression Test

Uniaxial compression tests are used to obtain approximate values of shear strength and settlement behavior of fine-grained soils at unconfined conditions. A vertical normal stress (σ_1) is applied to the specimen (cylindrical or cubic sample), while the stresses on the planes mutually perpendicular to the σ_1 direction ($\sigma_2 = \sigma_3$) are zero. The vertical stress is increased until the specimen fails, which determines the strength of the soil at the given water content. The results of the test can also be used to define the tensile strength of single soil aggregates (Section 3.3.6).

3.3.4.2 Confined Compression Test

Soil stress–strain relationships of undisturbed structured and homogenized soils with respect to volume change behavior are quantified in confined compression tests (*oedometer* tests). In contrast to uniaxial compression tests, the stresses σ_2 and σ_3 are undefined (rigid wall of the soil cylinder) and the respective strains are defined and equal to zero. Both time- and load-dependent changes in soil deformation are measured (recorded as settlement). The slopes of the virgin compression and the recompression line in a void ratio *e* versus log σ plot are referred to as the compression index ($C_c = -\delta e/\delta \log \sigma$) and swelling index ($C_s = -\delta e/\delta \log \sigma$), respectively. The transition from the region of overconsolidation (recompression) to normal consolidation (virgin compression) is defined by the precompression stress, which separates the stress range where soil deformation is considered fully elastic (i.e., reversible) from the stress range where soil deformation is elastoplastic (i.e., partly irreversible). Precompression stress (σ_p) is most frequently determined based on the method by *Casagrande* (Casagrande, 1936); however,

a number of alternative approaches are found in the literature. For a review of different σ_p estimates refer to Grozic et al. (2003).

3.3.4.3 Triaxial Test

Triaxial tests mimic in situ stress distributions and are most realistic since horizontal and vertical stresses are defined and adjustable. However, they are also more difficult to conduct and more laborious than, for example, *oedometer* tests, where a high number of samples can be measured, and, hence, spatial heterogeneity of natural soils is better reflected. Triaxial tests on the other hand have the advantage that both volume and shape changes are determined simultaneously on the same sample and that failure occurs at the naturally weakest plane, which is important for deriving material parameters used in modeling approaches. In triaxial tests, undisturbed cylindrical soil samples are loaded with an increasing vertical principal stress (σ_1), while the horizontal principal stresses ($\sigma_2 = \sigma_3$) are kept constant (equal to the cell pressure). Shear stresses occur in any plane other than those of the principal stresses. Shear parameters (cohesion and angle of internal friction) can be determined from the slope of Coulomb's failure line embracing the Mohr circles at failure for various combinations of σ_1 and $\sigma_2 = \sigma_3$ (e.g., Kézdi (1974), Mitchell (1993), Wulfsohn et al. (1998)). Due to aggregate deterioration and prevented drainage of excess soil water, the *Mohr–Coulomb failure line* is bent toward smaller slope values at higher mean normal stresses. However, the numbers of contact points, strength per contact point, and pore geometry also affect triaxial test results.

There are three types of triaxial tests: (1) In the consolidated drained (CD) test, the soil sample is equilibrated with the mean normal stresses prior to an increase in the vertical stress (σ_1); the pore water drains off when the decrease in volume exceeds the air-filled pore space. Therefore, the applied stresses are assumed to be transmitted as effective stresses via the solid phase. However, Baumgartl (1991) found an additional change in the pore water pressure during extended CD triaxial tests depending on soil hydraulic properties. Thus, shear speed and low hydraulic conductivity, high tortuosity, and small hydraulic gradients further affect the drainage of excess soil water and the effective stresses (Horn et al., 1995). (2) In the consolidated undrained (CU) test, pore water is prevented from draining off the soil as vertical stress increases. Thus, high hydraulic gradients occur and the pore water reacts as a lubricant with a low surface tension. Thus, in the CU test (considering total stresses), shear

TABLE 3.1 Methods of Determining Soil Strength

Method	Dimension	Derived	Soil Condition
Uniaxial compression	Pressure (Pa)		Homogenized soil, structured bulk soil, and single aggregates
Confined compression test	Pressure (Pa)	Precompression stress (Pa)	Homogenized soil, structured bulk soil
Triaxial test	Pressure (Pa)	Cohesion (Pa), angle of internal friction (°)	Homogenized soil, structured bulk soil, and single aggregates
Direct shear test	Pressure (Pa)	Cohesion (Pa), angle of internal friction (°)	Homogenized soil, structured bulk soil, and single aggregates

parameters are much smaller and pore water pressure values are much greater than those in the CD test. (3) The highest neutral stresses and, therefore, the lowest shear stresses are measured in the unconsolidated undrained (UU) test, where neither the effective stresses nor the neutral stresses are equilibrated with the applied principal stresses at the beginning of the test. Thus, cohesion and angle of internal friction in terms of total stresses are strongly dependent on the compression and drainage conditions during deformation. In terms of strength of agricultural soils under traffic, texture, pore water pressure (in unsaturated conditions referred to as soil matric potential), nature of aggregates, and soil structure determine the preference for a particular test.

3.3.4.4 Cyclic Compression Test

The theoretical concept of precompression stress as an indicator for soil stability is based on the assumption that in the elastic range of deformation (recompression line), there is no permanent volume change. This is not strictly true since even at load magnitudes below σ_p, there is always a small but yet noticeable volume change. While volume changes for a low number of loading events below the precompression stress mostly only insignificantly affect soil porosity, the situation may change for a higher number of load repetitions. In fact, the formation of a plow layer and the development of a platy soil structure are the result of numerous loading events rather than the product of once exceeding the precompression stress value (Peth and Horn, 2006b). Volume change behavior for repeated loading conditions can be investigated by *cyclic compression tests*. Such tests allow estimating soil compaction due to short- and long-term multiple machine passages or animal trampling in grazing areas (Peth and Horn, 2006a; Krümmelbein et al., 2008). Samples are measured in a standard oedometer device with a constant load applied for a number of load cycles (e.g., 100 cycles). Soil deformation expressed as change in void ratio follows a logarithmic trend with number of load cycles (Figure 3.9). A simple model can be used to predict the compression of a soil subject to the same load for multiple loading repetitions (Peth, 2004):

$$e(N) = -C_n \times \log N + e_u^1. \tag{3.19}$$

Here, e and N are the void ratio and number of loading cycles, respectively. The axis intercept e_u^1 denotes the void ratio in the unloaded condition after the first loading event. Only the following loading events are considered to belong to the cyclic loading process. The slope C_n in Equation 3.19 is referred to as *cyclic compressibility* and indicates the sensitivity of a soil toward cyclic compression. The higher C_n the higher is the compression under repeated loading.

3.3.5 Shear Strength Parameters

The shear strength parameters, cohesion (*c*), and angle of internal friction (φ), may be determined by triaxial tests as described above or in a direct shear test. During direct shear tests, the type
FIGURE 3.9 Compressibility as a function of repeated ("cyclic") loading. The slope C_n (cyclic compressibility index) denotes the sensitivity of the soil toward cyclic compression at the same magnitude of external load. (After Peth, S., and R. Horn. 2006b. The mechanical behavior of structured and homogenized soil under repeated loading. J. Plant Nutr. Soil Sci./Z. Pflanzenernahr. Bodenkd. 169:401–410.)

and direction of the shear plane, which is assumed to be affected only by normal and shear stresses, are fixed. Normal stress is applied to the specimen in the vertical and shear stress in the horizontal direction. To determine the Mohr–Coulomb failure line, at least four to five samples need to be tested each with a different normal stress. The maximum shear resistance (τ_{max}) is determined from a shear stress–displacement curve and plotted against the corresponding normal stress (σ_n). Plotting all pairs of τ_{max} versus σ_n gives the Mohr–Coulomb failure line in which the slope and intercept are the angle of internal friction (φ) and cohesion (*c*), respectively. As in triaxial tests, cohesion and angle of internal friction are influenced by shear speed and drainage conditions for a given soil.

3.3.6 Tensile Strength of Aggregates and Bulk Soil

Tensile strength of soils is a measure of the direct strength of interparticle bonds, which depend on chemical bonding, clay type and content, water potential (menisci forces), and organic matter. Also the internal geometry of particle arrangements and preexisting shrinkage cracks determine shear failure and crack propagation upon mechanical and hydraulic loads generating tensile forces. Tensile strength is an important indicator for the structural stability from the aggregate scale to the bulk soil level and a decisive factor for the preservation of physical quality of soils subject to mechanical stresses. The most widely used technique to measure tensile strength of soil aggregates is the *crushing test*. Soil aggregates are placed between two parallel plates in their most stable position (flat side downward) and the upper plate is loaded either with a weight (e.g., water dripping slowly into a bucket, Horn and Dexter, 1989, or by a load frame).

The force when failure occurs is recorded and tensile strength is calculated according to Dexter and Kroesbergen (1985):

$$Y = \frac{0.576 \times F}{d^2}, \tag{3.20}$$

where

   Y is the tensile strength
   F is the applied force
   d is the mean diameter of the aggregate given by

$$d = \frac{(d_x + d_y + d_z)}{3} \tag{3.21}$$

with indices *x*, *y*, and *z* denoting the aggregate diameter of the longest, intermediate, and shortest axes, respectively.

Other indirect techniques have been proposed to investigate crack growth and propagation in soils subject to tensile forces. One method is based on approaches adapted from fracture mechanics where crack formation and propagation are measured by so-called deep notch three-point bending tests (Hallett and Newson, 2001, 2005). Also direct tensile tests have been suggested to study crack propagation and tensile strength of soils, for example, using bone-shaped bulk soil samples that are torn apart by tension forces perpendicular to a predefined crack (Junge et al., 2000).

3.3.7 Other Methods to Determine Aggregate Stability

Aggregate stability may also be determined by wet sieving. Here, soil samples are prewetted to a given pore water pressure and then sieved through a set of sieves from 8 to 2 mm diameter. The difference between the aggregate-size distribution at the beginning and end of sieving under water for a given time is calculated as the mean weight diameter (MWD). This value is qualitatively related to aggregate strength and increases with increasing aggregate stability. The wettability of the solid interfaces has a pronounced effect on the test results in wet sieving and direct comparison with strength parameters derived from mechanical stress applications through polar loads is limited. Aggregate stability has also been measured by the application of ultrasonic dispersion techniques where aggregate stability can be expressed by the input of ultrasound energy resulting in the breakup of aggregates into smaller microaggregate units up to single particles (Raine and So, 1994). A comparison of different methods to determine aggregate stability is given by Baumgartl and Horn (1993).

3.4 Effect of Soil Structure on Soil Strength and Deformation Processes

As mechanical stresses are applied, soil deformation occurs first at the weakest point(s) in the soil matrix and further increases in stress resulting in the formation of failure zones. The strength of the failure zone is equal to the energy required to create a new unit of surface area or to initiate a crack (Skidmore and Powers, 1982) and is called the apparent surface energy (Hadas, 1987). Consequently, soil stability against shear or tensile stresses is related to strength distribution in failure zones. In principle, soil structure will be stable if the applied stress is smaller than the strength of the failure zone, that is, if the bond strength at the points of contact exceeds the shear or tensile stresses generated by external loads. If the resisting forces are smaller than the active forces, stresses are in disequilibrium and hence soil deformation will occur to generate more contact points until stress equilibrium is reached again. Reorientation of particles is accompanied by a change in soil structure and consequently functions. In extreme stress situations (especially high shear stresses) or when soil is subject to mechanical loads in unfavorable moisture conditions (near the liquid limit), soil structure may be almost completely returned to an immature state (homogeneous soil). In contrast to shear stresses that lead to volume constant deformation, normal stresses result in volume change, that is, compression, which is plastic as soon as the soil stability is exceeded. In situ stress conditions during field operations (traffic, soil–tool interactions) are generally characterized by a combination of both shear and compressive stresses.

3.4.1 Mechanical Properties of Homogenized Soils

If only mechanical properties of homogenized soils are compared, gravelly soils are less compressible than sandy or finer-textured soils (Horn, 1988), and any deviation of the particles from the spherical shape results in an increase in the shearing resistance and soil strength (Gudehus, 1981; Hartge and Horn, 1999). Ellies et al. (1995) found that the angle of internal friction for medium and coarse sands at comparable bulk density and water content but of different origins (quartz, basalt, volcanic ash, and shells) ranged from 25° to 50°. Soil strength also depends on the type and content of clay minerals and exchangeable cations. At the same bulk density and pore water pressure, compressibility of homogenized soil increases with clay content and decreases with soil organic-matter (SOM) content. Vice versa soils at the same clay content are more readily compressed at lower bulk density or higher moisture content. Cohesive forces between illite, smectite, and vermiculite are greater than for kaolinite, which in turn has a larger angle of internal friction because of its size and particle shape. Additionally, the higher the valency of the adsorbed cations and the higher the ionic strength of the soil solution, the greater is the shearing resistance under otherwise similar conditions (Yong and Warkentin, 1966; Mitchell, 1993).

Shearing resistance also increases depending on both the nature and content of SOM. In agricultural soils with the same physical and chemical properties, the mechanical parameters (precompression stress, angle of internal friction, and cohesion) are greater when the relative contents of carbohydrates, condensed lignin subunits, bound fatty acids, and aliphatic polymers are higher (Hempfling et al., 1990).

3.4.2 Mechanical Properties of Aggregated Soils

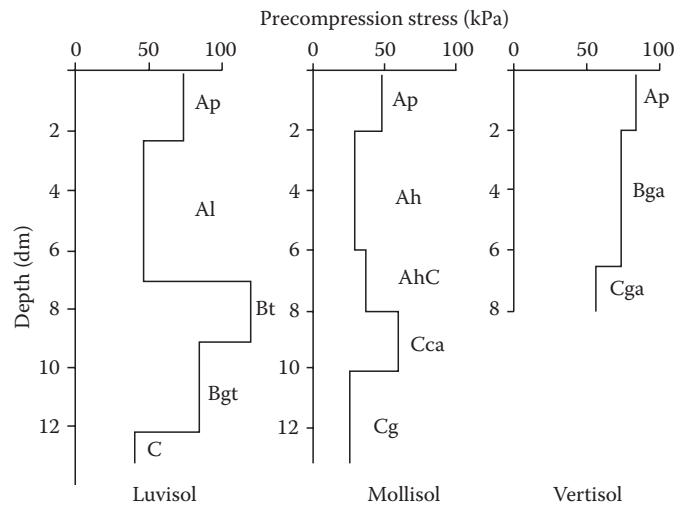
Mechanical strength of structured soils depends on aggregation and history of hydraulic stresses (degree of maximum predrying), as well as the shape and internal arrangement of particles, microaggregates, and voids. At comparable grain-size distribution, bulk density, and pore water pressure, soil strength increases with aggregation (i.e., coherent < prismatic < blocky < subangular blocky < crumbly). In the case of a platy structure, the strength depends on the direction of shear forces relative to the preferred orientation of the particles. In the direction of the elongated axes of aligned particles, shear strength is lower than perpendicular to it. This means that not only mechanical stresses are anisotropic but also strength properties that in turn are a function of aggregation. However, both the magnitude of previous hydraulic stresses (predrying intensity) and their dynamic changes determine soil strength. Therefore, mechanical properties also depend on the frequency of swell/shrink and wet/dry events and on the actual pore water pressure at the time of loading. Soils become stronger when redried and rewetted and when pore water pressure gradients over longer distances promote particle movement and rearrangement until entropy is minimized (Semmel et al., 1990). The effect of pore water pressure on strength itself is governed by the theory of effective stresses in unsaturated soils (e.g., *Bishop*'s effective stress equation (Equation 3.2)). It has been extended from the early considerations of *Terzaghi* (Terzaghi, 1936) for saturated soils; however, its application remains difficult since the evaluation of the parameter χ in Equation 3.2 is still complicated. It accounts for the tradeoff between pore water pressure (increases interparticle forces with curvature of menisci) and effective area of interparticle contact (when decreasing, the effect of pore water pressure is reduced). The interrelationship of pore water pressure and effective area of interparticle contact is structure dependent and hence also χ is related to structure and not as sometimes assumed purely a function of the degree of saturation. If the relative reduction in water-filled pores is smaller than the actual decrease in pore water pressure (more negative matric potential), soil strength increases while if the decrease in the effective surface of water menisci exceeds the decrease in matric potential (getting more negative), the effective stress of such drier soils gets absolutely smaller. In principle, soil strength is promoted by two different mechanisms: (1) the increase in strength results from an increase in the total number of contact points between single particles (i.e., an increase in effective stress) and (2) the increase in shear resistance per contact point (Hartge and Horn, 1984). Therefore, even if soil bulk densities are similar, strength properties may be quite different. Also freezing and thawing affect soil strength, because aggregates become either denser or they are destroyed by ice lens formation during freezing. The exfoliation process starts from the outer skin. Both effects are called soil curing, but result in completely different strength values and physical properties of the bulk soil (Horn, 1985b; Kay, 1990). Pedogenic effects on natural mechanical strength of three soils are illustrated in Figure 3.10. Luvisols derived from loess are characterized by clay


FIGURE 3.10 Precompression stress values for three soil profiles at soil matric potential of $\Psi_m = -6\,\text{kPa}$. (Modified from Horn, R. 1994b. Stress transmission and recompaction in tilled and segmently disturbed soils under trafficking, p. 53–87. *In* N.S. Jayawardane and E. Stewart (eds.) Subsoil management techniques. Lewis Publishers, Boca Raton, FL.)

illuviation, which results in strength decrease in the *Al* horizon and an increase in the *Bt* horizon due to aggregation. On the other hand, calcium precipitation in the Cca horizon of the mollisol also leads to a strength increase. In all three soils, the parent material (C horizon) was weakest although overburden pressure increases with soil depth suggesting the opposite should have been the case. This underlines the offset of soil strength parameters by pedogenic processes. On the other hand, anthropogenic processes such as annual plowing and tractor traffic may create very strong plow pan layers with precompression stress values similar to the contact pressure of a tractor tire or even higher (up to 300%) due to lug effects. The transition from the region of overconsolidation to the virgin compression line depends to a great extent on internal parameters and further on the hydraulic and mechanical stress history. In addition, strength decreases in the *Ap* horizon due to plowing and seedbed preparation can be observed until texture-dependent values are reached.

Pronounced strength decreases are also found in soil profiles that have been deep-loosened or deep-plowed (up to 60 cm) or loosened and/or mixed with other soil material. In the case of a partial deep loosening by a trenching slit plow (Reich et al., 1985; Blackwell et al., 1989), traffic must be restricted by the use of smaller machinery or controlled tracks perpendicular to the homogenized soil volume.

Soils with a well-developed vertical pore system are stronger than those with randomized or horizontal pore arrangements since elongated pores are more stable with their symmetry axis oriented in the direction of the major principle stress (σ_1) than perpendicular to it. Therefore, vertical (bio) pores are less prone to compression than oblique or horizontally oriented pores and, thus, untilled or minimum tilled soils are stronger than conventionally tilled soils (Horn, 1986).

Each soil deformation requires air-filled pore space and sufficiently high hydraulic conductivity during compression to drain off the excess pore water. The smaller the hydraulic conductivity, the hydraulic potential gradient, and the pore continuity, the more stable is the soil especially during short-term loading. In sandy soils, this effect is small and initial settlement equals the total strain. With increasing clay content, however, the proportion of initial to primary and secondary consolidation is reduced and time-dependent soil settlement becomes important. This results in an increase in precompression stresses for short-term loading due to an increase in pore water pressure that dissipates only slowly depending on the local hydraulic conductivity. Such drainage effects on the consolidation process are smaller in more strongly aggregated soils and with coarser soil textures.

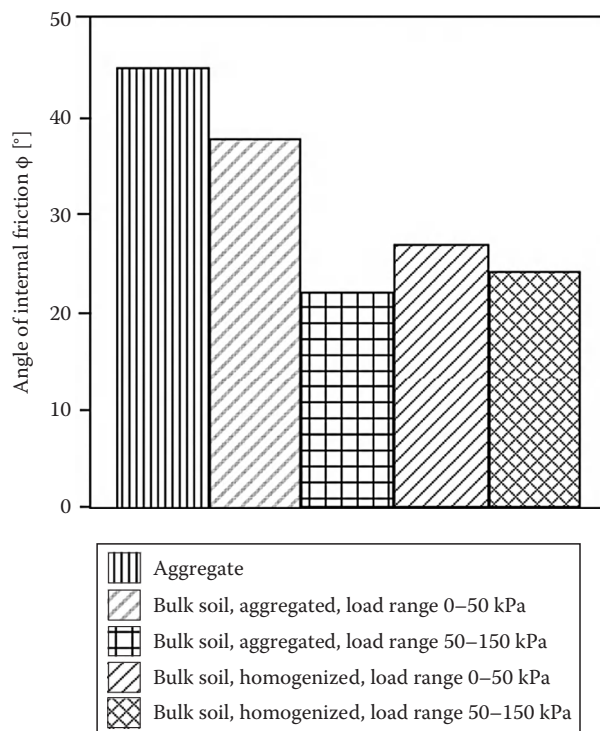
The development of structure generally results in increasing soil strength since the formation of secondary large pores is always accompanied by the development of denser aggregates. Although the aggregate assemblages carry the same stresses over fewer contact points, the aggregates themselves are more resistant to shear stresses. Strength differences may also result from changes in the angle of internal friction and cohesion as indicated in Figure 3.11 for a single aggregate, an undisturbed aggregate, and a homogenized bulk soil, respectively. More intense aggregation increases soil strength at comparable hydraulic stresses.


FIGURE 3.11 Changes in shear strength at constant soil matric potential $\Psi_m = -6\,kPa$ for various applied stress ranges for single aggregates, bulk soil, and homogenized material. (Modified from Horn, R., T. Baumgartl, R. Kayser, and S. Baasch. 1995. Effect of aggregate strength on changes in strength and stress distribution in structured bulk soils, p. 31–52. *In* K.H. Hartge and R. Stewart (eds.) Soil structure: Its development and function. CRC Press, Boca Raton, FL.)

Angle of internal friction for a single aggregate (~45°) is very high compared to bulk soil samples. However, aggregated bulk soil reveals higher friction angles than the homogenized soil at the same bulk density. This shear strength gain is lost when stresses exceed the overall stability of the aggregated sample leading to a reduction in the angle of internal friction to values similar for homogenized soil. When the maximum value of stress exceeds the maximum strength such that structure is homogenized, only texture-dependent properties remain.

3.4.3 Soil Deformation under Dynamic Stresses

Standard mechanical stability indicators such as shear strength parameters (ϕ and c) and precompression stress (σ_p) are without dispute suitable for characterizing the mechanical strength/stability of soils and to assess if significant irreversible volumetric and shear deformation under given stress conditions are likely to occur. Horn et al. (2005), for example, have derived stability maps on various scales down to farm level where sensitive and less sensitive areas are outlined, which could help farmers to avoid harmful subsoil compaction. We must, however, consider more in detail the repeated short-term loading because multiple loading events cumulatively add to the total compression, although concerning precompression stresses no further compression maybe expected. Zapf (1997), for example, argued that the increase in irreversible deformation of arable soil by agricultural machinery is not only related to the increasing mass of machines but also related to the increase in wheeling frequency. Peth and Horn (2006b) estimated that, based on the calculations of Olfe (1995), for an average-sized wheat-production farm in a time period of 5 years, the number of load repetitions may add up to 50 events for 85% of the field and up to 100 events for permanent wheeling tracks.

Cyclic compression tests allow estimating soil deformation due to repeated loading and hence assessing the effect of long-term field traffic on subsoil compaction. Similar to other strength parameters, cyclic compressibility (see coefficient C_n in Equation 3.19) for homogenous soils at the same bulk density is strongly texture dependent (Figure 3.12). The finer the texture and especially the higher the clay content, the higher is the sensitivity against cyclic compression (higher C_n values). Porosity changes with increasing number of loading cycles are significant and accumulate to up to ~3.0 vol% after 100 cycles (for sandy loam, Figure 3.12). Assuming that mostly larger pores are affected by compression, this would mean a reduction in air capacity by additional 3.0 vol%, although the applied load (40 kPa) was relatively low. Cyclic compressibility tests on undisturbed field samples reflect also the influence of structure and tillage management (Figure 3.13). Correlation between bulk density and C_n was higher for conventionally tilled soils and only weak for the conservation tillage system where C_n values were on an average lower at similar bulk densities. The lack of a strong correlation between bulk density and C_n suggests a stabilizing effect of structure. Some of the aggregated soils show during cyclic loading a stepwise compression curve with a few quasistable plateaus followed by stronger settlements until deformation is leveling off
FIGURE 3.12 Changes in porosity for different soil textures (homogenized samples) due to cyclic loading with a load of 40 kPa at the same initial bulk density (1.62 g cm⁻³). Samples have been equilibrated to a standard matric potential of −6 kPa prior to the tests. Note that the change in porosity after the first loading–unloading event is omitted here (for sand = 1.28, for silty sand = 1.22, and for sandy loam = 2.12 vol%). Error bars indicate standard deviation ($n = 14$). Corresponding C_n values are given in brackets (mean ± SD). (From Peth, S., and R. Horn. 2006b. The mechanical behavior of structured and homogenized soil under repeated loading. J. Plant Nutr. Soil Sci./Z. Pflanzenernahr. Bodenkd. 169:401–410.)
FIGURE 3.13 Correlation between initial soil bulk density and cyclic compressibility coefficients (C_n) of a haplic luvisol (Marienstein/Germany) with silt loam texture for different tillage systems: CT1 and CT2 are two different conventionally tilled sites; CnT is conservation tillage. (From Peth, S., and R. Horn. 2006b. The mechanical behavior of structured and homogenized soil under repeated loading. J. Plant Nutr. Soil Sci./Z. Pflanzenernahr. Bodenkd. 169:401–410.)

again (Figure 3.14). This behavior could be interpreted as stable aggregate units breaking under repeated loading just like steel may break due to material wear. Although these results still have preliminary character and certainly more systematic tests are needed, they demonstrate the importance of considering dynamic stress paths in soil testing in order to derive realistic estimates of compaction under field loading conditions.
FIGURE 3.14 Aggregate breakup during cyclic loading ("cyclic wear of aggregates"). (After Peth, S., J. Rostek, A. Zink, A. Mordhorst, and R. Horn. 2010. Soil testing of dynamic deformation processes of arable soils. Soil Till. Res. 106:317–328.)

3.5 External Mechanical Forces and Stress Distribution in Soils

3.5.1 Stress Application and Variations in the Contact Area

Any load applied at the surface is transmitted to the soil in three dimensions by the solid, liquid, and gas phases. If air permeability is high enough to allow immediate deformation of the air-filled pores, soil settlement is mainly affected by fluid flow. However, fluid flow may be delayed because changes in water content or pore water pressure depend on the hydraulic conductivity, gradient, and pore continuity. Thus, the intensity and form of pressure transmission are again affected by soil strength. In the following discussion, stress distribution in both homogenized soils and aggregated systems will be defined. Based on the theory of Boussinesq (1885) who solved the problem of a point load acting perpendicular on an infinite half-space consisting of homogeneous, isotropic, and linear elastic material, Fröhlich (1934) introduced a textural-dependent concentration factor (v_k) to give more "flexibility" to the original Boussinesq solution for determining stress propagation in soils. Under saturated conditions, v_k ranges between 3 for very strong material (which is defined as linear elastic and corresponds to the Boussinesq solution) and 9 for soft soil becoming higher with increasing clay content. In weak soils with high concentration factor, stresses are transmitted to greater depth but remain concentrated around the perpendicular line of the load center. On the other hand, in strong soils with low values of the concentration factor, stresses are transmitted more horizontally and shallower.

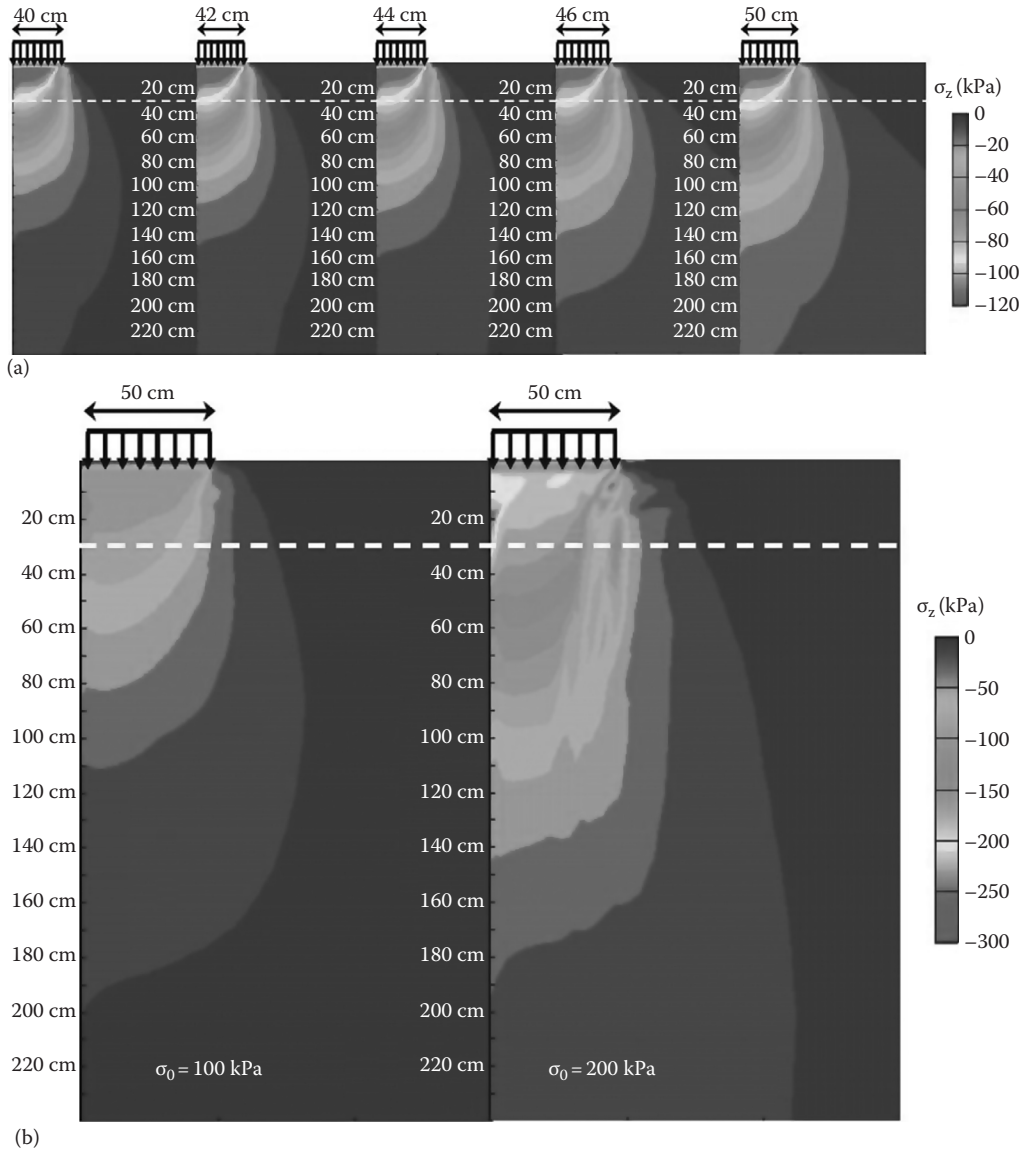
At the same contact pressure, stresses are transmitted deeper when the contact area is larger. Furthermore, stress distribution patterns in the soil are not only different for tire lugs and the intervening area but are also affected by the stiffness of the carcass (Horn et al., 1987). Thus, there are no well-defined equipotential stress lines in soils, but the concentration factor values must be related


FIGURE 3.15 (a) Stress distribution under a tire with the same ground contact pressure of 100 kPa but increasing contact area (tire size increases from left to right) and (b) for the same tire size (100 cm diameter) but increasing ground contact pressure (σ_0) due to higher wheel load, respectively. Vertical stresses σ_z (kPa) have been modeled with an FEM approach assuming rotational symmetry of the contact area (i.e., circular tire-soil contact shape). Note that only a part of the model domain is shown. The width of the model domain was 4.5 m to reduce boundary effects. The horizontal white-dashed line indicates the usual plowing depth of 30 cm. Mechanical properties for the topsoil and the subsoil were assumed to be the same. Following mechanical parameters were used for the simulation: cohesion $c = 10$ kPa, angle of internal friction $\phi = 20°$, stress-dependent bulk modulus $K(\sigma)\,\text{kPa} = 800 \times \sigma_m^{0.5} + 50$, stress-dependent shear modulus $G(\sigma)\,\text{kPa} = (270 \times \sigma_m^{0.5})(1 - (\tau/\tau_f)^{0.37}) + 50$, where the yield stress $\tau_f(\sigma_n) = c + \sigma_n \tan \phi$. For further details on material functions and parameters, see Section 3.2.3 and Richards and Peth (2009).

to precompression stresses in relation to applied stress and contact area for a given texture (DVWK, 1995). If additionally applied stresses do not exceed the internal soil strength defined by the precompression stress, the concentration factor is smaller as compared to the situation when the stresses result in a plastic deformation. The latter is defined by higher values (Berli et al., 2003).

The speed effect of wheeling, as well as the kind of stress application (tire, rubber belt tire-inflation pressure), affects the stress path at the soil surface and also causes enormous differences in the stress propagation inside the soil volume. It is well

understood that at a given surface load, the stress propagation reaches the deeper the larger the contact area and that at a given contact area stresses are transmitted deeper for higher ground contact pressures (Peth and Horn, 2004; Figure 3.15a and b).

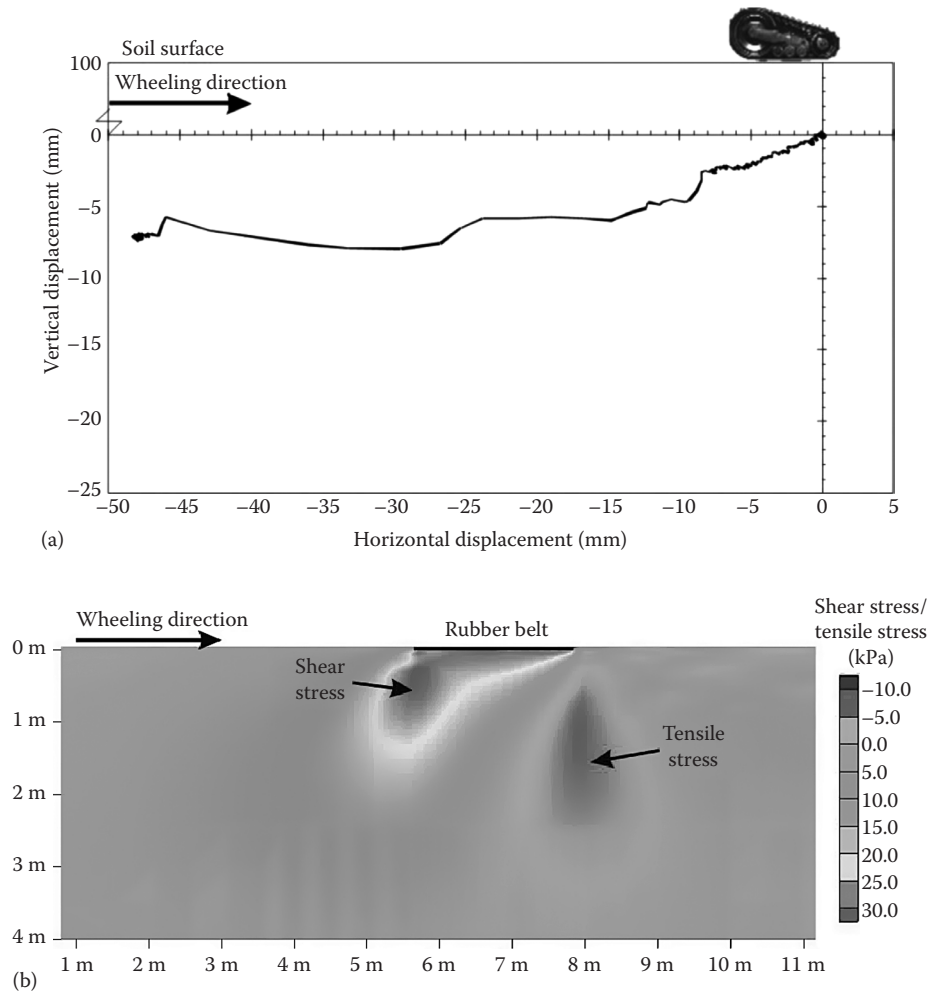
When we consider the stress vector field during wheeling, the tangential redirection of stresses increases with stronger wheel slip and less rigid tire or rubber belt (Figure 3.16a and b). Keller (2004), Arvidsson and Keller (2007), Cui et al. (2007), and Keller et al. (2007a) proved the effect of various tire forms and tire-inflation pressure on soil stress distribution and not


FIGURE 3.16 (a) Vertical and horizontal movement of a displacement sensor installed in situ at 10 cm depth during wheeling with a rubber belt tractor. (b) Modeled (FEM) distribution of shear/tensile stresses under a rubber belt tractor during wheeling. Note that material properties used for the FEM are not the same as for the site where soil displacement has been measured in situ (a). Simulated stress distribution has been conducted for a hypothetical case. Material properties and boundary conditions used in (b) were as follows: belt length = 240 cm, tractor weight = 12.6 Mg, ground contact pressure σ_0 = 67 kPa, horizontal stress transmitted via the belt = 32.5 kPa, cohesion c = 10 kPa, angle of internal friction ϕ = 20°, stress-dependent bulk modulus $K(\sigma)\,\text{kPa} = 800 \times \sigma_m^{0.5} + 50$, stress-dependent shear modulus $G(\sigma)\,\text{kPa} = (270 \times \sigma_m^{0.5})(1 - (\tau/\tau_f)^{0.37}) + 50$, where the yield stress $\tau_f\,(\sigma_n) = c + \sigma_n \tan \phi$. For further details on material functions and parameters, see Section 3.2.3 and Richards and Peth (2009).

only showed the heterogeneity of the stress distribution but also quantified the effect of changes in the tire forms and inflation pressure on stress distribution. Burt et al. (1989) already described the enormous heterogeneity in the stress distribution within the contact area that differed up to 300% and was higher beneath the lugs and the lowest in between them close to the middle part of the area while due to carcass effects it reached extremely high values at the outer edge of the tire.

The question about the effect of traffic on stress distribution and its consequences on soil properties remains, even after more than three decades of intensive discussion, still controversial, which is most often caused by different scientific views or interests in the subject. It is to be understood that the machine industry is mostly interested in the development of more effective and more powerful machines resulting in heavier traffic with higher wheel

load and wheel contact area. The benefits of new and smaller more intelligent self-steering GPS-controlled agricultural machines are still under debate, although it is a positive way to minimize the still increasing and deeper stress transmission into soils taking place when using conventional (heavier) machines. On the other hand, when soil scientists deal with traffic–soil interactions, they are mostly concerned about the effects of stress application on soil properties and the future effects for crop production, water infiltration, filtering and buffering, and groundwater recharge. Recently, enhanced greenhouse gas emissions have been more often associated with the interaction of soil stress and soil deformation, which results in changes in aeration and microbial activity. Legislation finally has to link both interests where stakeholders have to decide based on their administrative perspectives and given laws. The debate on soil use

and soil protection has resulted in Germany in the German Soil Protection Law (BBodSchG, 1998), while at European level such a law is still under discussion. However, the liability varies to a great extent even in between different provinces within Germany and the definition of main soil parameters (indicators) is not finalized (Horn and Fleige, 2009).

3.5.2 Stress Effects in the Soil

3.5.2.1 Internal Parameters

At a given bulk density and pore water pressure, applied stress at the soil surface will be transmitted deeper as silt and clay contents increase while stress attenuation will be greater in a smaller volume as the soil dries. For a given particle-size distribution, water content, and bulk density, stress attenuation will increase with increasing SOM content. Based on many stress distribution measurements in the field and in monoliths, a general correlation scheme involving texture, precompression stress, and tire contact area to derive the concentration factor v_k has been used to approximately predict the stress distribution in soils (DVWK, 1995); for more information see also Horn and Fleige (2003).

3.5.2.2 Structure Effects on Stress Attenuation

The effect of aggregation on stress distribution and its consequences for ecological parameters are well understood. Under in situ conditions for soils with the same internal parameters, stress attenuation is greater the more aggregated soils are. Concentration factor values expressed as precompression stress are smaller for better aggregated and drier soils (DVWK, 1995). Not only the pressure but also the size and shape of the contact area affect stress distribution in unsaturated structured soils.

Stress distribution calculations in a luvisol derived from loess under natural forest and its comparison with the identical computation under arable management show the effect of soil strength on stress attenuation (Figure 3.17a and b). Under natural forest, especially the clay-enriched Bt horizon with a prismatic–blocky structure (matric potential ~ −30 kPa) attenuated the applied stresses of the tractor and both combine harvesters while the topsoil (Ah- and the clay-depleted Al horizons), respectively, with a crumbly or coherent structure was deformed.

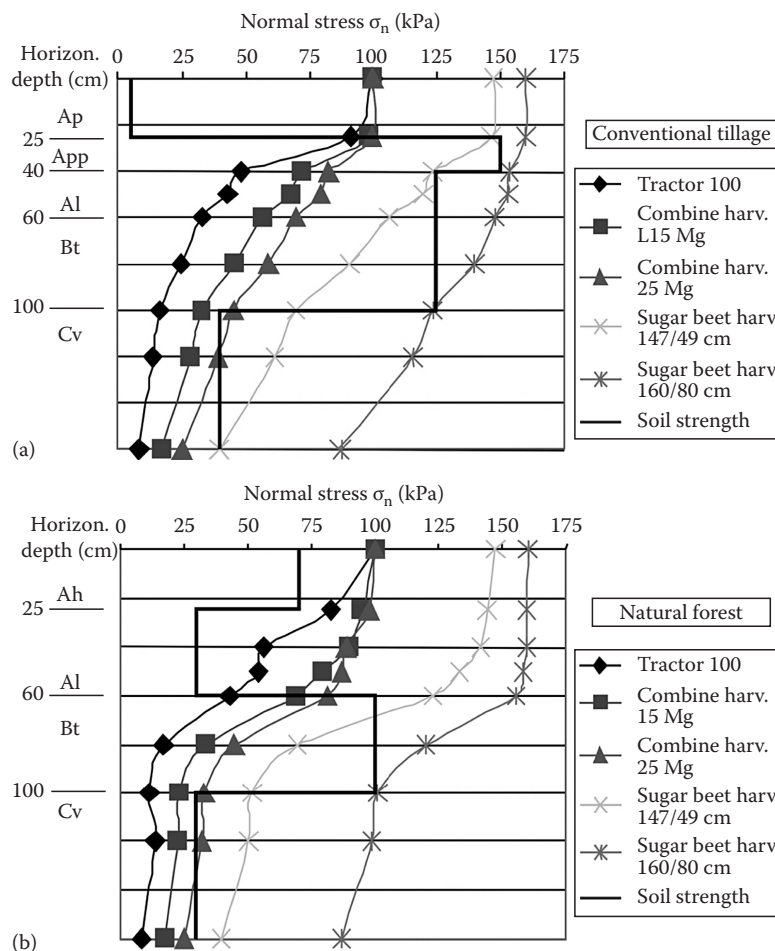
Under arable conditions, approximately 1/4th of the pores within the top 100 cm were lost compared with the forest site, which also resulted in higher precompression stress at all depths


FIGURE 3.17 Modeled stress distribution in a luvisol derived from loess under forest (b) and under conventional tillage (a). The concentration factors were defined according to the degree of aggregation.
FIGURE 3.18 Comparison of stress attenuation for different wheel loads and tire-inflation pressures in a luvisol derived from loess under conservation (a) and conventional tillage (b). Dashed and solid lines with symbols indicate stresses derived from SST (stress rate transducer) measurements; solid line without symbol indicates horizon-specific precompression stresses. (From Zink, A. 2009. Bodenstabilität und Auswirkungen dynamischer Lasteinträge auf physikalische Eigenschaften von Ackerböden unter konservierender und konventioneller Bodenbearbeitung. Ph.D. Thesis. Schriftenreihe Institut für Pflanzenernährung und Bodenkunde, Germany, No. 84, 180 pp. ISSN: 0933-680X.)

except for the Ap horizon and a more complete stress attenuation apart from the homogenized seedbed. However, the first introduction of the heavier sugar beet harvesters caused a deeper and a more intense soil deformation while exceeding the corresponding actual soil strength (Peth et al., 2006). The effect of stress attenuation depending on soil structure and strength (as a function of depth) can be also derived from Figure 3.18 (Zink, 2009). The luvisol derived from loess under long-term conventional and conservation tillage management shows limited stress attenuation at given wheel loads with and without reduced inflation pressure, which causes irreversible soil deformation (stresses exceed the precompression stress).

Repeated short-term stress application results in an increase in the matric potential and a higher water saturation within the various horizons. Consequently, the repeated short-term loading not only weakens the soil structure by deformation but also pumps additional soil water from deeper depths (repeated elastic rebound creates a suction mechanism), which further enhances soil deformation. Semmel (1993) could prove that due to repeated wheeling-induced soil softening, horizontal minor stresses decreased while the major vertical stress increased during 50 repeated wheeling events with a 3.7 Mg tractor. The soil softening was also reflected by reduced soil strength and an increase in the concentration factor due to repeated wheeling. The same processes also occur in grassland ecosystems under arid conditions during sheep trampling. Krümmelbein et al. (2008) could show that in grassland soils, which are intensely trampled during winter, soil strength is reduced due to "kneading," which negatively affected hydraulic properties. Also, tree harvesting in forest soils causes an intense increase in the precompression stresses, formation of deeper ruts, reduced aeration, and a restricted plant growth as a result of dynamic soil loading (Vossbrink and Horn, 2004; Horn et al., 2007b). The controlled traffic lane concept could prevent large-scale soil deformation by restricting mechanical stresses to defined lanes, hence protecting arable and forest land even during intensive future land use (Alakukku et al., 2003; Chamen et al., 2003; Watts et al., 2005).

An interesting aspect of soil deformation caused by extremely heavy loads is shown in Figure 3.19. During a first time wheeling event with a sugar beet harvester (35 Mg), a formerly formed rigid plow pan layer lying on top of a weaker subsoil may even be destroyed by breaking the platy structure due to shear stress concentrations in the plow pan (Fazekas, 2005; Peth et al., 2006).
FIGURE 3.19 Schematic sketch of stress-induced changes in the plow pan layer as a consequence of the initial wheeling with a heavy sugar beet harvester. (Modified from Fazekas, O. 2005. Bedeutung von Bodenstruktur und Wasserspannung als stabilisierende Kenngrößen gegen intensive mechanische Belastungen in einer Parabraunerde aus Löss unter Pflug- und Mulchsaat. Ph.D. Thesis. Schriftenreihe des Institut für Pflanzenernährung und Bodenkunde, Germany, No. 67, 170 pp. ISSN: 0933-680X.)

Repeated wheeling of such a site may then result in deeper stress penetration and consequently aggravates subsoil compaction.

3.5.3 Effect of Stress Application on Soil Strain

If external stress is smaller than internal soil strength, no deformation results and vice versa. However, because the latter includes soil compaction and shear processes, both the rut depth and the vertical movement of a given soil volume below the rut must be known if we want to distinguish between both processes. The extent to which soil deformation occurs during traffic and the extent to which various tillage implements (conventional/conservation) deform a soil at a given pore water pressure are shown in Figure 3.20. In the conventional tillage treatment in a loessial luvisol, passage of a tractor (front/rear wheel) results in a pronounced vertical (up to 8 cm) and horizontal forward and backward (up to 2 cm) displacement. Under conservation tillage, the same tractor results in smaller soil deformations because of a higher internal

(a)

(b)

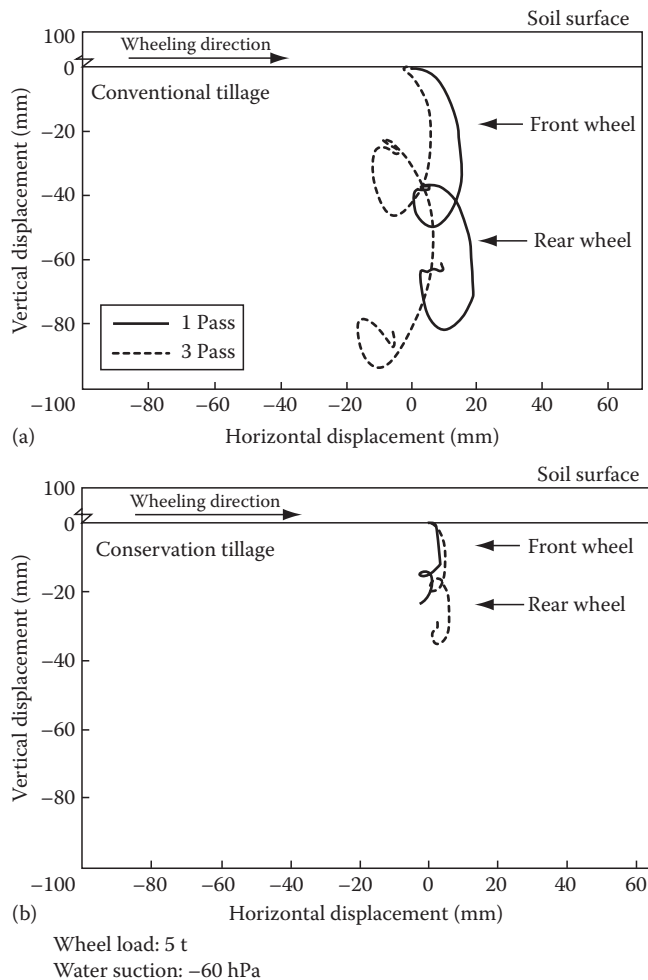
Wheel load: 5 t
Water suction: −60 hPa


FIGURE 3.20 Strain distribution in structured soils due to traffic. Particle movement is more pronounced in the conventionally tilled luvisol (a) while soil deformation is less intensive in the conservation tillage plot (b). (From Wiermann, C., D. Werner, R. Horn, J. Rostek, and B. Werner. 2000. Stress/strain processes in a structured unsaturated silty loam Luvisol under different tillage treatments in Germany. Soil Till. Res. 53:117–128.)
FIGURE 3.21 Vertical-elastic (reversible) and plastic (irreversible) soil displacement in a luvisol derived from loess for different wheel loads and management systems. Soil movement has been measured with a DTS/SST (displacement transmitter/stress state transducer system). (From Zink, A. 2009. Bodenstabilität und Auswirkungen dynamischer Lasteinträge auf physikalische Eigenschaften von Ackerböden unter konservierender und konventioneller Bodenbearbeitung. Ph.D. Thesis. Schriftenreihe Institut für Pflanzenernährung und Bodenkunde, Germany, No. 84, 180 pp. ISSN: 0933-680X.)

soil strength leading to a maximum vertical displacement of <4 cm after three traffic events and a much less pronounced horizontal displacement. With increasing aggregate development, soil strength increases and aggregate deterioration is less pronounced during displacement and alteration of the pore system due to the infilling of interaggregate pores by smaller particles. Nevertheless, all stresses that are not attenuated to levels below soil strength result in volume alterations, even if the applied stresses vary for different soil types, land uses, tillage systems, and environmental conditions. The intense effect of wheel load on soil strain down to 40 cm depth in luvisols derived from loess under conventional and conservation management depicts the sensitivity of stress application on changes in the pore system (Figure 3.21). With increasing wheel load at a given soil stress, the vertical height change is more intense under conventional than under long-term conservation tillage practice and affects also deeper soil depths irreversibly, which was also stated by Richards and Peth (2009).

3.6 Soil Deformation and its Effects on Physical and Physicochemical Properties

At mechanical failure, physical, chemical, and biological as well as physicochemical properties are affected. Stepniewski et al. (1994), Pagliai and Jones (2002), Lipiec and Hatano (2003), Lipiec et al.

(2004), and Horn et al. (2006) summed up the present knowledge and underline the detrimental effects of soil deformation on physical, chemical, and biological soil properties and functions. Larink et al. (2001) and Langmaack et al. (2002) emphasize the stress effect on biological activity and regeneration after stress application and observed an intense change in species abundances. Numerous papers defined in addition the effect of soil deformation of penetration resistance, which is often primarily linked with root growth, but these data can also be used to define in situ "stresses at rest" as a measure of the actual compression status of plots, fields, or even landscapes (Horn et al., 2007a).

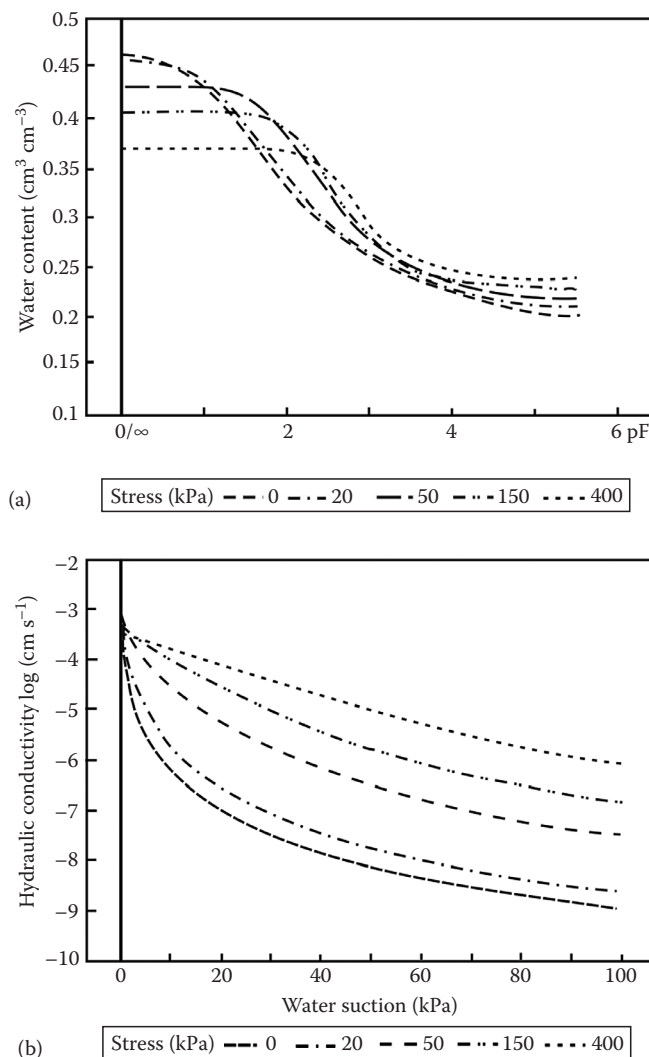
Concerning changes in hydraulic properties under static loading, which are of main importance for numerous processes, it becomes obvious that both capacity properties like pore-size distribution (water retention characteristic) and intensity relations like the unsaturated hydraulic conductivity function show a severe change with applied stress (Figure 3.22; Horn et al., 1995).


FIGURE 3.22 Change in water retention characteristic (a) and unsaturated hydraulic conductivity (b) as a function of applied mechanical stresses.
FIGURE 3.23 Changes in redox potential as a function of load in two soils depths. (Data from Horn, R. 1985a. Auswirkung mechanischer Belastungen auf die Redoxpotentiale von 3 Bodenmonolithen–ein Laborversuch. J. Plant Nutr. Soil Sci./Z. Pflanzenernahr. Bodenkd. 148:47–53.)

Identical diagrams are also prepared for gas diffusion (Glinski and Stepniewski, 1985), thermal properties, and also redox reactions where a more intense stress dependency with remaining smaller values is shown when the internal soil strength is exceeded (Figure 3.23). A direct link between the mechanical stress application and increased denitrification rates was presented by Flessa et al. (1998) and Liu et al. (2007).

However, not only these general changes, but also alterations in vector properties of, for example, the hydraulic conductivity (Doerner, 2005; Doerner and Horn 2009), reflect the strong effect of stress–strain processes on soil functions. Wheeling-induced formation of platy structures results in a pronounced horizontal anisotropy of the hydraulic conductivity and intensifies lateral water and solute movement, which enhances soil erosion and nutrient export. Particularly, shear-induced strain processes lead to changes in transport functions also with consequences for gas fluxes and compositions due to more pronounced flow path tortuosities and reduced pore connectivity, which can be observed down to the aggregate scale (Ball et al., 1999; Peth et al., 2008).

3.7 Modeling Soil Deformation and Coupled Processes

In unsaturated structured soils, hydraulic, thermal, and/or gas transport processes must be mutually linked in order to fully account for deformation-induced changes in soil functions. Especially, hydraulic and mechanical processes are tied up closely. This is evident for example in the action of hydraulic stresses during shrinking and swelling and their consequences for soil strength or in the role of pore water pressures on consolidation and compression (effective stress theory). On the other hand, soil deformation and reorientation of particles and aggregates influence pore-size distribution and pore-network geometries. Hence, hydraulic conductivity within the matrix and structural pores is changed, which finally affects, in turn, hydraulic stresses and subsequent deformation behavior.

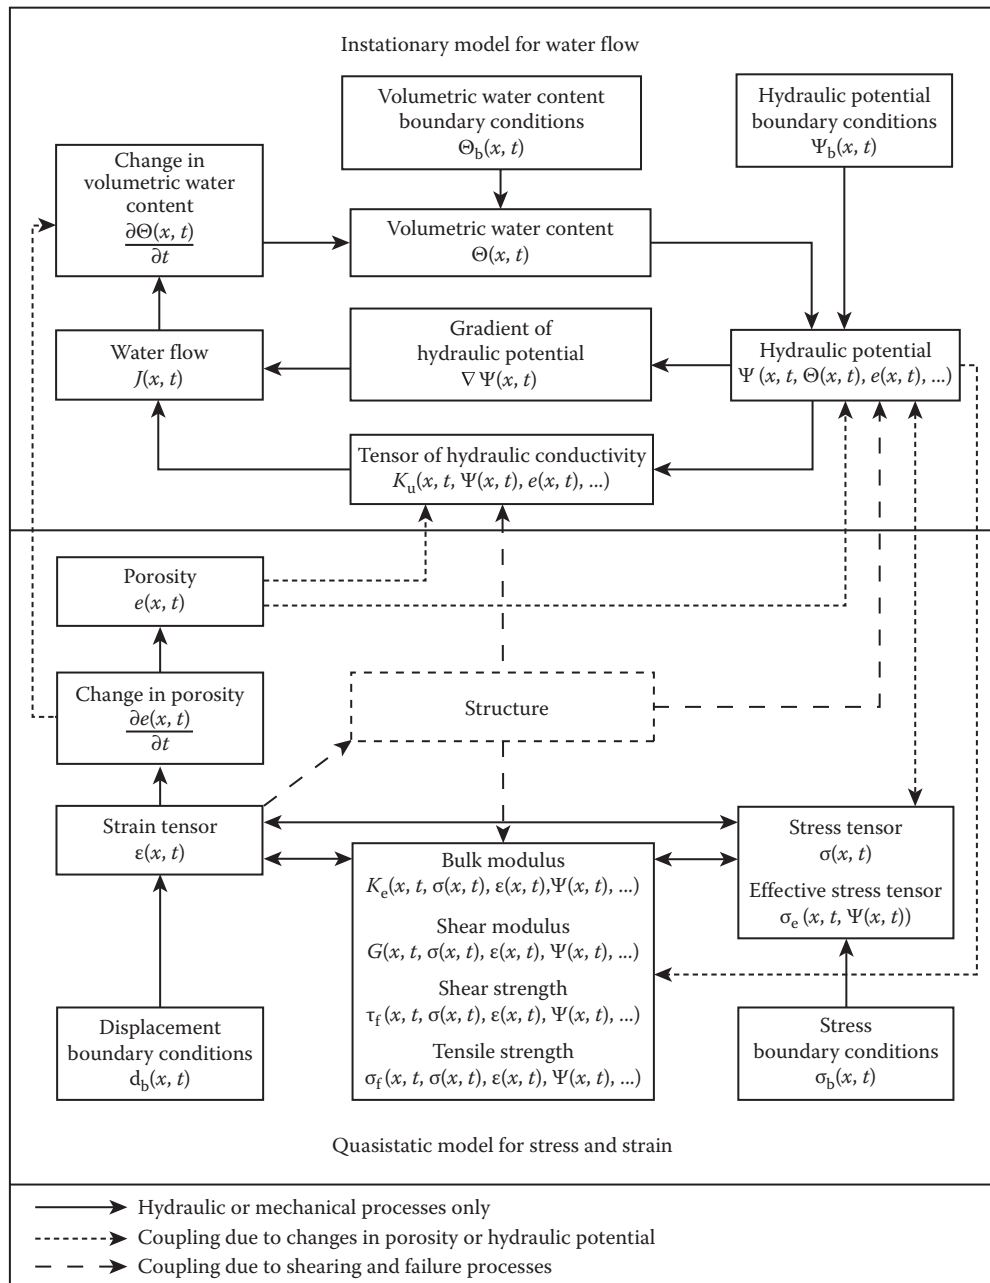
The mathematical equations for water, gas, and heat transport in soils and the effects of tillage on changes in structure are available (Jury et al., 1991). However, often physical soil behavior is still investigated by treating either process in isolation rather than accounting for their interdependency (Kirby, 1994; Kirby et al., 1997; Keller et al., 2007b). Richards (1992) proposed a finite element model that was able to interactively couple load deformation and flow processes in unsaturated and swelling soils. The model was later further improved by Gräsle (1999) and tested by simulating standard mechanical laboratory tests. The modeling concepts Richards developed over decades are summarized in Richards and Peth (2009), including some model applications for civil engineering and soil science problems. A detailed conceptual framework for modeling coupled soil mechanical and hydraulic processes in soils is represented in Figure 3.24 (Gräsle et al., 1995). O'Sullivan and Simota (1995)


FIGURE 3.24 Schematic representation of a coupled hydraulic elastoplastic model to define and quantify coupled processes in soils. (From Gräsle, W. T. Baumgartl, R. Horn, and B.G. Richards. 1995. Interaction between soil mechanical properties of structured soils and hydraulic process—Theoretical fundamentals of a model. Balkema 2, p. 719–724. *In* E.E. Alonso and P. Delage (eds.) Proc. First Int. Conf. Unsaturated Soils/ UNSAT'95, September 6–8, Paris, France. Balkema, Rotterdam, the Netherlands.)

and Defossez and Richard (2002) have reviewed some soil compaction models and discussed problems when combining them with environmental impact and crop production models.

3.7.1 Deformation and Failure

This process describes the load/deformation/failure response of soil to a change in stress, strain, and/or displacement with all other factors held constant. It includes (1) nonlinear elastic behavior of the material as a function of stress and its history and matric potential (Richards, 1978); (2) changes in initial stress or strain as a result of swell/shrink behavior caused by changes in soil water suction, solute content, or temperature (Richards, 1986); (3) stress/strain path dependency or hysteretic behavior in load-deformation response (Richards, 1979); and (4) shear and tensile failure with dilatance or compression and with strain softening.

3.7.2 Coupling Soil Mechanical and Hydraulic Processes

During any kind of soil deformation, changes in hydraulic properties will occur, which is an important factor influencing the further deformation process as pointed out in the effective stress equation of *Terzaghi* Equation 3.1. In addition, changes in soil stress due to swelling or shrinkage will also cause changes in soil water potential. This effect of stress on water potential is sometimes referred to as the stress potential or the stress component of field measurements of soil water suction (Richards, 1986). Load-deformation analysis must therefore be coupled with changes in soil water potential, including subsequent water flow (Figure 3.24). The displacements can also be used to calculate the new geometry and material velocities for the analysis of water flow in soils undergoing strain. Such analysis can be also extended to 3D flow problems, which are of interest in the plow pan and in well-structured horizons below.

3.7.3 Example Application of the Finite Element Model

Modeling soil stiffness for various horizons with differing mechanical properties and the overall stress–strain relationships of a complete soil profile requires the derivation of stress-dependent moduli (bulk K and shear G modulus, see Section 3.2.3). The mechanical material properties defined by K and G may be determined by back-analyzing consolidation and shear test data (Richards et al., 1997). In this approach, the soil test is simulated with an FEM using an initial estimate of the material parameters, which are subsequently modified until a good agreement between modeled and measured test data is achieved. An example where a consolidation test has been simulated is shown in Figure 3.25.

Such stress-dependent mechanical soil properties may be used to calculate stress distribution under loads within a soil profile more accurately accounting for differences in soil stiffness and
FIGURE 3.25   Measured and simulated settlement of a consolidation test (oedometer). The ordinate has been scaled to the original height of the tested undisturbed soil sample (30 mm). (From Richards, B.G., and S. Peth. 2009. Modelling soil physical behaviour with particular reference to soil science. Soil Till. Res. 102:216–224.)

strength with depth including the mechanical history of the soil (precompression stress). A comparison of measured stress (stress state transducer [SST]) data from a traffic experiment on a conservation tillage plot (shallow chiseling up to 8 cm, luvisol derived from glacial till) with stress distributions simulated by FEM using the mechanical parameters derived for three soil horizons of the corresponding soil profile is shown in Figure 3.26. Simulations including and excluding the plow pan layer, which was encountered in 20–40 cm soil depth, indicate that no good agreement between the measured and simulated stresses was obtained when the plow pan was not included in the FEM simulation. In contrast, if the corresponding mechanical data of the plow pan were included in the simulation, then a reasonably good agreement between the stress measurements and model prediction would be obtained (Figure 3.26). Similar examples of the simulation of stress distributions under tires using this FEM approach in conjunction with parameter estimations from mechanical laboratory testing are given in Peth et al. (2006) and Richards and Peth (2009).

3.8 Concluding Remarks

1. Mechanical soil properties are useful indicators for the development and physical quality of soil structure.
2. The determination of soil strength requires the measurement of volumetric stress and strain.
3. Structure development in arable and forest soils always results in increased soil strength. With increased aggregation, strength increases and the characteristics of the water retention curve become more pronounced.
4. In structured soils, hydraulic properties of inter- and intra-aggregate pores are different. Differences in hydraulic conductivity, plant available water, and air capacity become more pronounced as structure development increases.
FIGURE 3.26 Determined and modeled vertical stress versus depth in a luvisol derived from glacial till under conservation tillage (type Horsch). The properties of a plow pan layer, which had been created until 1989 and which had a thickness of 20 cm (from 20 to 40 cm were not (a) and were (b) included in the model). (Data from Kühner, S. 1997. Simultane Messung von Spannungen und Bodenbewegungen bei statischen und dynamischen Belastungen zur Abschätzung der dadurch induzierten Bodenbeanspruchung. Ph.D. Thesis. Schriftenreihe des Institut für Pflanzenernährung und Bodenkunde, Germany, 39, 190 pp. ISSN: 0933-680X.)

In addition, root penetrability is reduced into aggregate interiors but may be enhanced in cracks of the interaggregate pore space.

5. The increase in strength with decreasing pore water pressure depends on the pattern of the water retention curve for single aggregates and bulk soil.

6. With increasing degree of aggregation, pore water pressure at the same water content in the bulk soil becomes more negative. Single aggregates are always stronger than the bulk soil or the homogenized material. This is related to smaller increases in pore water pressure during loading and higher aggregate bulk densities. Shear strength parameters (angle of internal friction and cohesion) are always higher for single aggregates than for bulk soil. However, as soon as applied stress exceeds the internal soil strength, single aggregate and aggregated bulk soils will become homogenized accompanied by a decline in strength.

7. Soil strength is strongly affected by spatial differences in pore water pressure. Hydraulic properties of single aggregates and their arrangement in the bulk soil are therefore most important for predicting soil strength and stress distributions in soils. Stress attenuation, stress distribution, and soil deformation due to loading under running wheels or belts can vary to a great extent depending on in situ soil conditions, machinery parameters, and frequency of loading. Soil deformation should therefore be considered as a dynamic rather than a static process.

8. Structure development always involves reduced accessibility to exchange sites for soil solutions, retarded exchange processes, and stronger chemical disequilibrium. Only at the lowest entropy (at an increased accessibility), structured soils become macroscopically homogeneous. With reduced pore water potential (reduced flux rate), the exchange process becomes more complete. At higher saturations, anaerobic soil volumes in aggregates become more extensive for longer periods. Thus, soil physicochemical properties vary intensely throughout the year.

9. The coupled analysis of multifunctional and interactive processes in unsaturated structured soils is an important topic for future soil research but very complex. Long-term soil stability involves materials, which are unsaturated, nonlinear hysteretic, and the soil composition changes with time. During tillage operations, many physical and mechanical properties are altered requiring a more precise definition of the actual conditions and their expected temporal changes.

10. Measurements and modeling of coupled ion and water fluxes through unsaturated structured soils are most important for future work because aggregation affects ion diffusion, dispersion, and mass flow. Changes in pore systems and functions are also affected by mechanical stresses. Thus, model coupling is required and could enhance the estimate of time-dependent effects on nutrient, heavy metal, or pesticide transport through structured soils also including the effect of drying or wetting or deformation (compaction) processes.

4.1 Introduction

Water in soil occupies pore spaces that arise from the physical arrangement of the particulate solid phase, competitively and often concurrently with the soil gas phase (Chapters 1, 2, and 8). While hidden from casual view, substantial volumes of water are commonly stored in soils. For example, one hectare of medium-textured soil 1 m deep and having field capacity water content of 20% by volume may store sufficient water to fill 4000 200 L barrels. This reservoir serves as a resource pool for plant growth and a substantial buffer in areas having scattered or sporadic precipitation. Other soil organisms, many of which are beneficial, especially to biogeochemical cycling, also rely heavily on the water-holding characteristics of soils for their existence. On the other hand, soil water is a highly dynamic entity, exhibiting substantial variation in both time and space (Western et al., 2002). This is particularly true near the soil surface and in the presence of active plant roots. Changes in soil water content and its energy status affect many soil mechanical properties including strength, compactibility, and penetrability, and may cause changes in the bulk density of swelling soils. The liquid-phase characteristics affect the soil gaseous phase and the rates of exchange between these phases, as well as other important soil properties such as the hydraulic conductivity that governs the rate of water and soluble chemical flow.

The purpose of this chapter is to introduce the basic concepts related to the amount and energy state of water in soil. These concepts are prerequisite to quantify and manage soil water storage, to obtain predictions concerning rates and directions of water flow and solute transport, to utilize soils as building or foundation materials, and for many other purposes. The term soil water is used here to represent the soil liquid phase, which is typically a water solution containing dissolved salts, organic substances, and gases.

The water status in soils is defined by (1) the amount of water in the soil or soil water content (θ), and (2) the force by which water is held in the soil matrix, soil energy content or soil water potential (ψ). These soil water attributes are related to each other through a function known as the soil water characteristic (SWC).

4.2 Soil Water Content

Many agronomic, hydrologic, and geotechnical practices require knowledge of the amount of water contained in a particular soil volume (Robinson et al., 2008b; Vereecken et al., 2008). Some of the most common methods used to characterize and determine soil water content, on a mass or volume basis, in the laboratory or in situ will be described.

4.2.1 Definitions

4.2.1.1 Soil Water Content on Mass Basis (Gravimetric)

Mass or gravimetric soil water content is expressed relative to the mass of oven dry soil according to

$$\theta_m = \frac{\text{water mass}}{\text{dry soil mass}} = \frac{(\text{wet soil mass}) - (\text{dry soil mass})}{\text{dry soil mass}}, \qquad (4.1)$$

and has units of kg kg^{-1} or other consistent mass units.

4.2.1.2 Soil Water Content on Volume Basis

It is often desirable to express water content on a volume basis. The volumetric water content (θ_v) is defined as the volume of water per bulk volume of soil:

$$\theta_v = \frac{\text{volume of water}}{\text{bulk volume of soil}} = \frac{(\text{mass of water/density of water})}{\text{sample volume}}. \qquad (4.2)$$

It also represents the depth ratio of soil water (i.e., the depth of water per unit depth of soil). The conversion between gravimetric and volumetric water contents requires knowledge of the soil dry bulk density (ρ_b), which is the ratio of oven dry soil mass to its original volume, and the density of water. The conversion formula is given by the following:

$$\theta_v = \theta_m \frac{\rho_b}{\rho_w}, \qquad (4.3)$$

where ρ_w is the density of water (1000 kg m^{-3} at 20°C). Alternatively, a soil sample of known original volume may be processed as in the gravimetric method, and θ_v determined from Equation 4.2.

4.2.1.3 Water Content on Relative Saturation Basis

An additional means of characterizing the soil water content is in terms of the degree of saturation:

$$\Theta = \frac{(\text{volume of water-filled pore space})}{\text{total volume of soil pore space}} = \frac{\theta_v}{\theta_{vs}}, \qquad (4.4)$$

where θ_{vs} is volumetric soil water content under completely water-saturated conditions. This index ranges from zero in completely dry soil to unity in a saturated soil. The degree of saturation is also commonly termed effective saturation or relative water content.

4.2.1.4 Soil Water Storage

It is often convenient to express the quantity of soil water in a specific soil depth increment in terms of soil water storage or equivalent depth of soil water (units of length). Equivalent depth of soil water, D_e (m), is calculated as $D_e = \theta_v \times D$, where D is the soil depth increment (m) having volumetric water content θ_v. This quantity is useful to relate aboveground water dimensions of rainfall, irrigation, or evaporation (L) to belowground dimensions (θ_v, m^3 water m^{-3} soil). For example, one may wish to quantify changes in soil water content arising from addition of water by rainfall or loss of water by evaporation (Chapter 6). A useful rule of thumb is that 1 L of water delivered to 1 m^2 of soil is equivalent to a 1 mm depth increment of water. For suitable accuracy, it is often necessary to sum the equivalent depth relationship over discrete soil depth layers having distinct water contents:

$$D_e = \sum_{i=1}^{n} \theta_{vi} D_i, \qquad (4.5)$$

where i denotes depth increments.

4.2.2 Measurement of Soil Water Content

4.2.2.1 Thermogravimetry

This is a direct and destructive method whereby a soil sample is obtained by augering or coring into the soil; its volume need not be known. The sample is weighed at its initial wetness and then dried to remove interparticle absorbed water, and some, but not always all structural water trapped within clay lattices known as crystallization water. The conventional protocol is to oven dry the samples at 105°C until the soil mass becomes stable; this usually requires 24–48 h or more, depending on the sample size, wetness, and soil characteristics (texture, aggregation, etc.). The difference between the wet and dry weights is the mass of water held in the original soil sample (Section 4.2.1.2). Despite the somewhat arbitrary specification of a standard oven temperature (105°C) and the variable drying period (depending on specific conditions), the gravimetric method is considered the standard against which many indirect techniques are calibrated. The method is not without bias and/or error, however, and Gardner (1986) discussed some sources of these including the potential for water loss between sampling time and initial weighing, precision of the three weights involved (wet, dry, and tare), and the unknown amount of soil texture-dependent residual water associated with the clay fraction.

The primary advantages of gravimetry are the direct and relatively inexpensive processing of samples. The shortcomings of this method are its destruction of the sample location, labor- and time-intensive nature, the time delay required for drying (although this may be shortened by use of a microwave rather than conventional oven, the methodology has not yet been standardized), and the fact that the method is destructive thereby prohibiting repetitive measurements within the same soil volume.

4.2.2.2 Neutron Scattering

This is a nondestructive but indirect method commonly used for repetitive field measurement of volumetric water content (Greacen et al., 1981). It is based on the propensity of H nuclei to slow (thermalize) high-energy fast neutrons. A typical neutron moisture meter consists of (1) a probe containing a radioactive source that emits high-energy (2–4 MeV) fast (1600 km s^{-1}) neutrons, as well as a detector of slow neutrons; (2) a scaler to electronically monitor the flux of slow neutrons; and optionally (3) a data logger to facilitate storage and retrieval of data (Figure 4.1a). The radioactive source commonly contains a mixture of ^{241}Am and Be at 10–50 mCi. The ^{241}Am emits β particles that strike the Be and cause emission of fast neutrons.

When the probe is lowered into an access tube, fast neutrons are emitted radially into the soil where they collide with various atomic nuclei. Collisions with most nuclei are virtually elastic, causing only minor loss of kinetic energy by the fast neutrons. Collisions with H nuclei, which have similar mass of neutrons, cause a significant loss of kinetic energy and slow down the fast neutrons (consider a marble [neutron] colliding with a similarly sized ball bearing [H nucleus] vs. a stationary bowling ball [larger atomic nucleus]). When, as a result of repeated collisions, the speed of fast neutrons diminishes to those at ambient temperature (about 2.7 km s^{-1}), with corresponding energies of about 0.03 eV, they are called thermalized or slow neutrons. Thermalized neutrons rapidly form a cloud of nearly constant density near the probe, where the flux of the slow neutrons is measured by the detector. The average loss of the neutrons' kinetic energy, thus the relative number of slow neutrons, is
FIGURE 4.2 A neutron moisture meter calibration relationship.

therefore proportional to the amount of H nuclei in the surrounding soil. The primary source of H in soil is water; other sources of H in a given soil are assumed to be constant and are accounted for during calibration. Although several non-H substances including C, Cd, Bo, Cl, and Li, which may be present in trace amounts in some soils, may also thermalize fast neutrons, these may generally also be effectively compensated through soil-specific calibration.

Calibration of the neutron probe is therefore required to account for background H sources and other local effects (soil bulk density, trace neutron attenuators), and is conveniently achieved by paired measurements of soil water content and neutron probe counts. The calibration curve (Figure 4.2) is usually linear and relates θ_v to slow neutron counts or count ratio (CR):

$$\theta_v = a + b(CR), \tag{4.6}$$

where CR is the ratio of slow neutron counts at a specific location in the soil to a standard count obtained with the probe in its shield. For many soils, the calibration relation is approximately the same. Use of the count ratio rather than raw slow neutron counts compensates for the slow decay of the radioactive source over time.

The sphere of influence about the radiation source varies between about 15 cm (wet soil) and approximately 70 cm (very dry soil), depending on how far fast neutrons must travel in order to collide with a requisite number of H nuclei. An approximate equation for the radius of influence (r, in cm) as a function of soil wetness is (IAEA, 1970):

$$r = 15(\theta_v)^{-1/3}. \tag{4.7}$$

Thus, the neutron-scattering method is unsuitable for measurement near the soil surface because a portion of the neutrons may escape the soil. Advantages of this method include the ability to repeatedly measure θ_v at the same locations, averaging of the measured water content over a substantial soil volume, moderate equipment cost (generally about $4000–$6000), and the ability to measure soil water content at multiple depths and locations using the same equipment. Limitations or disadvantages include

(a)   (b)
FIGURE 4.1 An illustration of (a) a neutron probe device for measuring soil water content; symbols r_D and r_W represent different radii of measurement in dry and wet soils and (b) an electromagnet-based sensor using frequency domain reflectometry (Diviner 2000, Sentek Sensor Technologies, Stepney, Australia, with permission) to determine soil water content in an access tube.

the radiation hazard and attendant licensing requirements, relatively poor (and uncertain) spatial resolution, unsuitability for near-surface measurements, and the soil-specific calibration requirement.

4.2.2.3 Electric and Dielectric Methods

Measurement methods based on changes in soil electrical properties, due to changes in soil water content, have been used for decades (Smith-Rose, 1934; Babb, 1951), mostly in the area of agriculture and exploration geophysics. Background information concerning such applications may be found in a number of sources, including Olhoeft (1985), who addressed low-frequency electrical properties of porous media, Selig and Mansukhani (1975), who discussed early attempts to use resistance and capacitance techniques for soil water content measurements, and Hoekstra and Delaney (1974) concerning soil dielectric properties at very high frequencies. Presently, the most common electrical approaches for soil water content measurement may be grouped according to (1) time domain dielectric methods (Topp et al., 1980; Robinson et al., 2003), (2) capacitance methods (Dean et al., 1987; Paltineanu and Starr, 1997), (3) fixed frequency methods (Blonquist et al., 2005a), (4) resistance methods (Spaans and Baker, 1992; Leib et al., 2003), (5) geophysical electrical methods (Robinson et al., 2008a), and (6) remote-sensing methods (Moran et al., 2004).

Determination of dielectric properties is the physical principle that underlies many of these methods to determine water content. In the megahertz region of the electromagnetic spectrum, the dielectric values for solid, water, and air are relatively frequency independent (Figure 4.3). As the dielectric value of water is ~80 and that of solid and air is ~5 and 1, respectively, the proportion of water in a porous material has a dominant effect on the effective dielectric value (ε_{eff}). Two basic approaches have

been used to establish the relationship between ε_{eff} and θ_v. The first approach is empirical, whereby mathematical expressions are simply fitted to observed data without using any particular physical model. For example, Topp et al. (1980) found good agreement using a third-order polynomial between apparent dielectric constant (κ_a) and θ_v for a range of soils:

$$\theta_v = -5.3 \times 10^{-2} + 2.92 \times 10^{-2} \kappa_a - 5.5 \times 10^{-4} \kappa_a^2 + 4.3 \times 10^{-6} \kappa_a^3,$$

(4.8)

where κ is used to differentiate a measured value from the intrinsic material value ε_{eff}. This relationship provides adequate description for many mineral soils and for the water content range $\theta < 0.5$ (which covers the entire range of interest in most mineral soils), with an estimation error of about 0.013 for θ_v. However, Equation 4.8 fails to adequately describe the $\kappa_a - \theta_v$ relationship for water contents exceeding 0.5, and for organic rich soils, mainly because the Topp et al. calibration was based on experimental results for mineral soils and concentrated in the range of $\theta_v < 0.5$.

The second approach uses dielectric mixing models and the volume fraction of each of the soil phases to derive a predictive relationship between ε_{eff} and θ_v. In many soils $\kappa_a = \varepsilon_{eff}$, but as bulk soil electrical conductivity (ECa) increases so κ_a may diverge from ε_{eff} on an instrument-dependent basis (Kelleners et al., 2005). Such physically based approaches vary in their degree of complexity and have been presented by a number of authors (Dobson et al., 1985; Friedman, 1998; Cosenza et al., 2003).

Of the physically based models, Robinson et al. (2005) presented a layer model for coarse-textured soils. The result was a formula for determining water content based on ε_{eff}, the measured porosity φ, and the saturated (ε_{sat}) and dry (ε_{dry}) dielectric values.
FIGURE 4.3 A frequency domain diagram showing the permittivity/dielectric spectrum of water, the real part (ε') indicating energy "storage," and the imaginary part (ε'') indicating energy "loss." Data are presented for sand and for clay with varying degrees of saturation. The change in clay permittivity response with frequency is called dielectric dispersion. The boxes with symbols indicate the approximate frequency and bandwidth for the corresponding sensing methods.

Assuming a value of 2.8 for ε_{dry}, the model only requires that the porosity and ε_{sat} be known to determine the water content.

$$\theta = \varphi \left(\frac{\sqrt{\varepsilon_{eff}} - \sqrt{\varepsilon_{dry}}}{\sqrt{\varepsilon_{sat}} - \sqrt{\varepsilon_{dry}}} \right). \tag{4.9}$$

A more sophisticated version of the model was presented in Robinson et al. (2005), where additional mixing models were used to calculate ε_{sat} and ε_{dry}, resulting in a physically based model with no fitting parameters that accurately described the $\varepsilon_{eff} - \theta_v$ relationship in media with different solid-phase dielectric values. The advantages of the mixing model approach are that it is based on physics and is therefore instrument or sensor independent and it provides the flexibility to include variable mineral phase dielectric values, temperature and frequency effects, and geometry and porosity effects. This is illustrated for a range of porosity in Figure 4.4.

Clay minerals, especially the 2:1 smectites and vermiculites, can give a frequency dependent dielectric response (Figure 4.3). As a result, they can give $\varepsilon_{eff} - \theta_v$ responses that diverge from standard empirical models such as Equation 4.8, generally giving lower ε_{eff} values for a respective value of θ_v. De Loor (1968) presented a model to describe the effective dielectric value (ε_{eff}) of the soil, which assumes a consistency of isotropically mixed plate-like particles, suitable for describing clays. The model can take two forms, a simplified version including solid, water, and air phases:

$$\theta = \frac{3(\varepsilon_s - \varepsilon_{eff}) + 2\varphi_s(\varepsilon_a - \varepsilon_s) - \varepsilon_{eff}\varphi_s(\varepsilon_s/\varepsilon_a - 1)}{\varepsilon_{eff}(\varepsilon_s/\varepsilon_{fw} - \varepsilon_s/\varepsilon_a) + 2(\varepsilon_a - \varepsilon_{fw})}, \tag{4.10}$$
FIGURE 4.4 The dielectric water content relationship modeled using the approach described in Robinson et al. (2005). The different lines indicate the change in calibration due to the change in porosity.

and the one applied by Dobson et al. (1985) and Dirksen and Dasberg (1993), which adds a "bound" water phase, written as

$$\theta = \frac{\begin{array}{c}(3(\varepsilon_s - \varepsilon_{eff}) + 2\theta_{bw}(\varepsilon_{bw} - \varepsilon_{fw}) + 2\varphi_s(\varepsilon_a - \varepsilon_s) \\ + \varepsilon_{eff}\theta_{bw}(\varepsilon_s/\varepsilon_{fw} - \varepsilon_s/\varepsilon_{bw}) - \varepsilon_{eff}\varphi_s(\varepsilon_s/\varepsilon_a - 1))\end{array}}{(\varepsilon_{eff}(\varepsilon_s/\varepsilon_{fw} - \varepsilon_s/\varepsilon_a) + 2(\varepsilon_a - \varepsilon_{fw}))}, \quad \theta > \theta_{bw}, \tag{4.11}$$

where

φ_s is the solid volume fraction

subscripts of ε define the solid phase, s, gas phase, g, free water phase, fw, and bound water phase, bw (~4.2)

The volumetric bound water content, θ_{bw}, assumes a monomolecular layer of tightly bound water of a thickness $\delta = 3 \times 10^{-10}$ m spread over the soil-specific surface area, S ($cm^2\ g^{-1}$), for a bulk density, ρ_b (g cm^{-3}) (i.e., $\theta_{bw} = \delta \times \rho_b \times S$).

Due to the broad applicability of these models for understanding measurements made using time domain reflectometry (TDR), insertion probes, ground penetrating radar (GPR), and remote sensing, significant effort has been made in trying to improve our understanding of the dielectric properties of porous media. Recent attempts to better understand the dielectric behavior of soils and porous media include, particle-size distribution (Robinson and Friedman, 2001), particle geometry (Friedman and Robinson, 2002; Chen and Or, 2006), soil temperature (Or and Wraith, 1999), frequency dependence (Chen and Or, 2006), and dielectric phase configuration in aggregated media (Miyamoto et al., 2003; Blonquist et al., 2006). For a long time, bound water was proposed as the physical reason for the lower dielectric responses of clay soils (Jones and Or, 2003), but more recent literature suggests that particle shape, orientation (Jones and Friedman, 2000), and phase configuration (Blonquist et al., 2006) must also be considered.

4.2.2.4 Time Domain Reflectometry and Time Domain Transmissometry

Progress in devices for accurate measurement of reflected electromagnetic signals traveling along transmission lines led to the introduction of several measurement methods for soil dielectric properties using transmission lines embedded in the soil, such as TDR (Topp and Ferré, 2002; Robinson et al., 2003). TDR measures the apparent dielectric constant of the soil (κ_a) surrounding a TDR probe, at microwave frequencies from megahertz to gigahertz (Figure 4.3). The propagation velocity (v) of an electromagnetic wave along a transmission line (TDR probe) of length L embedded in the soil is determined from the time response of the system to a pulse generated by the TDR cable tester (Figure 4.5). The propagation

Time domain reflectometry unit
FIGURE 4.5 Schematic diagram of a TDR instrument attached via a coaxial cable to a three-rod TDR probe.

velocity (v = 2L/t) is a function of the apparent dielectric response of the soil according to

$$\kappa_a = \left(\frac{c}{v}\right)^2 = \left(\frac{ct}{2L}\right)^2, \tag{4.12}$$

where

  c is the velocity of electromagnetic waves in vacuum (3×10^8 m s^{-1})

  t is the travel time for the pulse to traverse the length of the embedded TDR probe in both directions (down and back)

A comprehensive body of literature now exists on TDR, and especially the electrode sampling volume (Ferre et al., 1998).

The main advantages of TDR over other methods for repetitive soil water content measurement are (1) superior accuracy to within 1% or 2% of θ_v, (2) minimal calibration requirements (in many cases soil-specific calibration is not needed), (3) no radiation hazards associated with neutron probe or gamma attenuation techniques, (4) excellent spatial and temporal resolution, and (5) simple to obtain continuous soil water measurements through automation and multiplexing (Baker and Allamaras, (1990)). Limitations of the TDR method include relatively high equipment expense, limited applicability under highly saline conditions due to signal attenuation, and the soil-specific calibration required for soils with high clay or organic matter contents. Severe attenuation of TDR waveforms in the presence of high salinity and/or some clays having high surface area and surface charge may interfere with, or even preclude, water content measurements.

Time domain transmission (TDT) sensors have more recently emerged (Blonquist et al., 2005b) as low cost, stand-alone sensors that have comparable measurement characteristics to TDR. These sensors are analogous to TDR, but rather than measuring the reflected signal, they measure the travel time around an electrode loop buried in the soil. Utilizing SDI-12 digital technology, they represent a new generation of multifunctional soil moisture sensors, also capable of determining bulk soil ECa and soil temperature.

4.2.2.5 Capacitance Probes

The electrical capacitance of two electrodes inserted in the soil is dependent upon the soil dielectric constant. The basic relationship between the soil dielectric constant and the electrical capacitance between two parallel plates of area A and spacing d is

$$C = \frac{A\varepsilon^* \varepsilon_0}{d}, \tag{4.13}$$

where

  ε^* is the relative complex dielectric constant of the soil, which contains both real (ε') and imaginary (ε'') components (Figure 4.3), with $\varepsilon^* = \varepsilon' - i\varepsilon''$, $i = \sqrt{-1}$

  ε_0 the dielectric constant of free space = 8.854×10^8 F m^{-1}

Note that the relative dielectric constant (ε^*) is the ratio of the complex dielectric constant to that of free space = $\varepsilon^*/\varepsilon_0$. Capacitance devices for field water content measurement are often based on annular electrode design rather than parallel plates (Kutilek and Nielsen, 1994; Fares and Polyakov, 2006) to facilitate depth measurements down boreholes (Dean et al., 1987; Figure 4.1b).

Commercial capacitance soil water gauges often use a resonant LC circuit relating changes in resonant frequency of the circuit to changes in the soil capacitance (Kelleners et al., 2004). Some gauges use a more direct capacitance bridge method to determine the unknown soil capacitance. Among the common capacitance-based measurement systems capable of soil water content profiling are the Sentry 200-AP (Troxler, NC) evaluated by Evett and Steiner (1995), which uses access tubes and a permanently installed modular bank of sensors (EnviroSCAN, Sentek, Australia) evaluated by Paltineanu and Starr (1997).

Advantages of capacitance methods include their lack of radiation hazard and lower expense than transmission line approaches such as TDR. However, research indicates greater sensitivity to bulk soil ECa and salinity (Kelleners et al., 2005). They also share the neutron probe's variable and uncertain measurement volume, and annular air gaps around sensors that utilize access tubes can cause substantial measurement errors.

Hence, buried probe designs seem to perform more reliably at present than those inserted into soil access tubes. Finally, capacitance methods share similar issues of relating the measured dielectric constant to soil water content as do other dielectric-based approaches.

4.2.2.6 Fixed Frequency Insertion Probes

Several new sensors and measurement methods are based on combinations of capacitive, reflective, and frequency-shift principles, all of which are governed by the soil dielectric properties. This trend appears highly promising for the development of accurate and cost-effective sensors for soil water content measurement. Examples of such stand-alone sensors (Figure 4.6) are the ThetaProbe (Gaskin and Miller, 1996) operating at about 100 MHz (Delta-T Devices Ltd, Cambridge, U.K.); the 50 MHz Hydra Probe (Campbell, 1990; Seyfried and Murdock, 2004; Stevens, Beaverton, OR); the 5 MHz ECH2O EC-20 probe (McMichael and Lascano, 2003; Decagon Devices, Pullman, WA), and newer sensors such as the Delta-T SM200 and WET sensors (Delta-T Devices Ltd, Cambridge, U.K.) both of which operate around 20 MHz and an array of Decagon Devices sensors including the EC-5, 10-HS, EC-TM, and 5TE, which all operate at 70 MHz frequency (Decagon Devices, Pullman, WA).

4.2.2.7 Electrical Resistivity Methods

Changes in the electrical resistivity of soils with changes in water content (and with soluble ionic constituents) have been used to develop simple and inexpensive sensors to infer soil water status. These sensors usually consist of concentric or parallel electrodes embedded in a porous matrix and connected to lead wires for measurement of electrical resistance within the sensor's porous matrix. The commonly used term gypsum block arises from early models that were in fact made of gypsum (Bouyoucos and Mick, 1940), and from the practice of saturating the matrix of many sensors made from alternative materials with gypsum to buffer local soil ionic effects. The sensor is embedded in the soil and allowed to equilibrate energetically with the soil solution. The matric potential of water in the sensor is estimated from the measured electrical resistance through previously determined calibration of the sensor itself (electrical resistance vs. matric potential). Under equilibrium conditions, the sensor matric potential is equal to the soil water matric potential; however, the sensor water content may be different than that of the soil. Hence, these measurements are often used to infer soil water matric potential from which the soil water content may be estimated based on a known relationship between these quantities (Gardner, 1986). With appropriate calibration for a particular soil (sensor electrical resistance vs. soil water content), the sensor can also be used to infer soil water content directly (Kutilek and Nielsen, 1994). The main advantages of electrical resistance sensors are their low cost and simple measurement requirements. Measurements may be obtained using a simple resistance meter or more conveniently acquired automatically using a data logger. On the other hand, the usual requirement for specific calibration of each individual sensor and for each soil to obtain acceptable accuracy, and lack of sensitivity under wet conditions, render this measurement method appropriate mostly as a qualitative indicator of soil water status (Spaans and Baker, 1992; Leib et al., 2003).

4.2.2.8 Geophysical Methods

The need for water content measurement at intermediate scales, such as the field to small watershed scale (Western et al., 2002), is driving an interest in using geophysical methods to bridge the gap between point measurements, using sensors such as TDR, and spatial measurements, using remote-sensing methods (Robinson et al., 2008b). Methods such as GPR, electrical resistivity imaging (ERI), and electromagnetic induction (EMI) have all been used to determine the spatial patterns of water content. Unlike many point sensors, where the operation and interpretation have become routine, geophysical methods still require a firm degree of user skill in both operation and interpretation. However, they offer the advantages of providing more spatially dense data and are non- or minimally invasive. Nevertheless, both ERI and EMI measure bulk soil ECa, with all the associated problems accompanied by a determination of water content from approximate direct-current (DC) electrical measurements. In addition, GPR uses unguided waves that can make soil water content interpretation more difficult. As a result, the data from geophysical imaging are often termed "soft data" and used as an aid to help interpret more spatially sparse point measurements.

GPR measures electromagnetic wave propagation time through the ground (Huisman et al., 2003a), utilizing the transmission and reflection of high frequency (1 MHz–1 GHz) electromagnetic waves within the soil. It offers the advantage
FIGURE 4.6 Array of different electromagnet-based sensors, which use dielectric measurement techniques to determine soil water content. Sensors include (1) TDR probe, (2) Acclima TDT, (3) Campbell Scientific 650 sensor, (4) Delta T ML2x sensor (Theta probe), (5) Stevens Water Hydra Probe sensor, (6) Decagon Devices 5TE sensor, (7) Decagon Devices EC-5 sensor, (8) Decagon Devices 10HS sensor, (9) Delta T Devices WET sensor, and (10) Delta T Devices SM200 sensor. Measurement techniques include travel-time analysis (1, 2, and 3), capacitance measurements (4, 6, 7, 8, 9, and 10), and impedance measurements (5).

of obtaining rapid on-the-go measurement, with penetration depths dependent on operation frequency and bulk soil ECa. Low frequencies usually equate to greater depths of penetration, while soil ECa values >1 dS m^{-1} (smectitic and saline soils) may attenuate the signal to such an extent that no valuable information is obtained (Weihermuller et al., 2007). A variety of methods have been adopted to determine water content from GPR data and are reviewed in Huisman et al. (2003a) and Annan (2005a, 2005b). Methods for determining water content include estimation of ground wave velocity (Hubbard et al., 2002; Huisman et al., 2003b); common offset profiling (Lunt et al., 2005); common midpoint measurements (Greaves et al., 1996); and surface reflectivity (Redman et al., 2002; Serbin and Or, 2004).

Both ERI (Samouelian et al., 2005) and EMI (Sheets and Hendrickx, 1995) determine water content by exploiting changes in soil ECa brought about by changes in water content. However, soil ECa is temperature, texture, and solute dependent, which can make interpretation difficult. Skilled users try to minimize certain factors, such as temperature effects by measuring at the same time during the day on repeated days, and by avoiding measurements at the hottest times. Determination of water content in soils with few, or no, retained cations, such as many highly weathered tropical or coarse-textured soils, often remains beyond the limits of these techniques.

The ERI method uses a low-frequency alternating-current to determine the electrical resistivity. Electrodes are evenly spaced in soil, often 0.25 to more than 5 m apart along a transect, and the resistivity is measured between different pairs of electrodes (Samouelian et al., 2005). By increasing the spacing between the measurement electrodes, greater depths of exploration can be achieved. By measuring multiple electrodes simultaneously, a 2D transect can be rapidly obtained. Successful application has been demonstrated using ERI for water content determination along transects by Michot et al. (2003) and Amidu and Dunbar (2007).

EMI instruments are configured with a receiver at one end and a transmitter loop at the other. The transmitter is energized and creates magnetic field loops that penetrate into the ground. These magnetic loops produce electrical field loops that in turn create a secondary magnetic field. At low induction numbers, the combined primary and secondary magnetic fields measured in the receiver are proportional to the bulk soil ECa (McNeill, 1980). As a result, EMI is noninvasive and can be linked to a GPS and field computer for the collection of spatial field data. The use of EMI to determine water content was initially reported by Kachanoski et al. (1988). Due to the instrument sensitivity to water and clay contents, Abdu et al. (2008) have proposed using the instrument to estimate soil moisture storage in small watersheds.

4.2.2.9 Remote-Sensing Methods

Remote-sensing methods may be vehicle, aircraft, or satellite based. They offer the ability to measure a large spatial area that is often more appealing to hydrologists in view of the scales at which they work (Moran et al., 2004). Airborne or spaceborne

measurements also tend to be cost effective and allow measurements in isolated terrain. Dielectric remote-sensing methods can be divided into "passive" and "active" methods.

Passive methods rely on the sun illuminating the ground surface and measure the naturally emitted radiation from the ground and do not work when it is cloudy. The radiation is measured using an instrument called a radiometer (Njoku and Entekhabi, 1996), and of growing interest are the systems that can be building or vehicle mounted. The soil emits radiation that increases with temperature and is termed the soil emissivity. In the microwave region, the dielectric value of the soil, as well as the surface geometry or roughness, affects how closely the surface resembles a perfect emitter or blackbody. As a result of the dependence of emissivity on dielectric properties, water content has a strong impact on measurements (Schmugge et al., 1974; Hallikainen et al., 1985). The amount of surface soil contribution to the emission varies with wavelength or frequency, becoming thinner as frequency increases. Measuring at a frequency of 1.4 GHz, the emitted radiation is considered sensitive to the upper 3–5 cm (Laymon et al., 2001).

Active sensing methods usually have a source to illuminate the soil surface and measure the response. Measurements using active methods are also depth dependent, according to measurement frequency, with L-band (1–2 GHz) being considered optimal for soil moisture determination (Entekhabi et al., 2004). Like passive for similar frequencies, the L-band active methods are considered to represent a response from the upper 5 cm of soil. One of the major advantages for the active method is that it does not rely on the soil surface being illuminated by the sun and can operate in almost all weathers. This has led to greater investigation of ground-based methods using horn antennas (Lambot et al., 2004, 2006; Serbin and Or, 2004).

Common to both measurement methods is the use of the data to determine soil moisture, and increasingly data assimilation methods are being developed to determine dynamic soil moisture behavior (Ni-Meister, 2008). Data assimilation allows the merging of observations with a system-dynamic model so that an improved estimate of the soil moisture state can be achieved. The direct data insertion approach (Jackson et al., 1981) takes remotely sensed soil moisture data and inserts them into the dynamic model when available. However, it does assume that remotely sensed observations give the "true" moisture content. More recent developments include the use of the extended Kalman filter, which is a sequential data assimilation tool, providing an optimal estimate for current and future states of a linear system. Hydrological processes are often nonlinear and so efforts have been made to linearize hydrological processes so that soil moisture data can be used (Walker and Houser, 2001).

4.2.2.10 Heat Pulse Probes

Determination of water content using soil thermal properties is becoming increasingly popular. Water content can be determined from the volumetric heat capacity (C_{soil}) or from the soil thermal conductivity (λ_{soil}). The soil volumetric heat capacity can be determined from the sum of the heat capacities of soil

solid, liquid, and gaseous phases (De Vries, 1963). Campbell (1985) introduced a simplified model for mineral soils C_{soil}, which disregards the heat capacity of air:

$$C_{soil} = C_s(1 - \varphi) + C_w\theta, \quad (4.14)$$

where

C is the heat capacity with subscripts w and s for water and solid phases respectively

φ is the porosity

Given the measurement of C_{soil} using a sensor, θ can be determined given the values of C_s and C_w from calorimetric methods (Kluitenberg, 2002). Water content determined from thermal conductivity, like ECa and dielectric properties, is dependent on the pore-scale geometry of the granular material (De Vries, 1963; Campbell, 1985), and is thus soil specific.

Campbell et al. (1991) proposed the dual-probe heat pulse (DPHP) method as a way of determining soil thermal properties. The method can measure the C, λ, or thermal diffusivity, α, from which θ can be determined. A short heat pulse is applied from a heater in one of the sensor needles and the temperature response is measured in a second needle separated by a short distance. The method has now been tested extensively in the laboratory (Bristow et al., 1993; Bristow, 1998; Basinger et al., 2003) and in field soils (Tarara and Ham, 1997; Heitman et al., 2003).

4.2.2.11 Emerging and Other Technologies

Laboratory investigations have resulted in a number of techniques emerging that are based on sound and light transmission. Brutsaert and Luthin (1964) and Mack and Brach (1966) were the first to report the sensitivity of acoustic wave propagation to soil water content. Recent developments include work by Adamo et al. (2004) and Blum et al. (2004) with acoustic tomography to study unsaturated flow. Recently, Lu (2007) proposed that the acoustic properties are more closely related to the matric potential of the soil than to the water content and thus provide a means to determine matric potential over a wide range. The use of light, in particular, measurements of changes in the refractive index, has proved a valuable laboratory technique for measuring 2D water flow in Hele-Shaw cells. Tidwell and Glass (1994) demonstrated that using a light source behind a cell and measuring the transmission the spatial distribution of water content in the cell can be determined.

Nuclear magnetic resonance (NMR) was first demonstrated in 1946 (Purcell, 1952; Bloch, 1953). Gummerson et al. (1979) were quick to adapt this to imaging unsaturated water flow in porous media. Bottomley et al. (1986) later used the technology to image the water content in root systems. The imaging method utilizes the fact that the hydrogen nucleus (^{1}H) possesses the strongest nuclear magnetic moment. These nuclei are randomly aligned in the absence of a strong magnetic field. On the application of an external magnetic field, the magnetic moments align with the field, antiparallel or parallel. An excess of antiparallel alignment provides a detectable macroscopic magnetization.

The modulus of the magnetization vector aligned with the external field is proportional to the number of ^{1}H nuclei in the sample. Assuming that water content is proportional to the number of ^{1}H nuclei, the proportion of water can be determined. Hinedi et al. (1993) demonstrated this linear relationship for granular media in the laboratory and subsequently the technique has been increasingly applied to soils by a number of researchers (Bird et al., 2005). Field NMR instruments have been developed for industrial applications and are described in Wolter and Krus (2005). The one-sided access (OSA)-NMR system (Perlo et al., 2005) is noninvasive and can be placed flat on a surface, measuring water content to a depth of 5–30 mm. Recent advances have also been made by the oil industry with the development of borehole NMR (Kleinberg and Jackson, 2001). The advantage of these methods is the ability to obtain additional information on the structure of the porous media (Song et al., 2000).

A critical constraint to advancing field-based process hydrology is the lack of spatially dense data to monitor changes in water content in time and space. Wireless sensor networks are developing as a new technology that allows sensors to be distributed in space, and wirelessly beam back measurements over radio links to a computer, so that real-time monitoring in time and space can be obtained (Akyildiz et al., 2002; Martinez et al., 2004). Soil moisture monitoring networks are emerging. Cardell-Oliver et al. (2005) presented a novel reactive soil moisture network that captures data with greater frequency in response to rainfall events. Some of the challenges faced in design and implementation are considered in Robinson et al. (2008b).

Other methods for soil water measurement include gamma ray attenuation techniques using dual-probe apparatus for bulk density and water content, x-ray computed tomography, and field techniques such as distributed fiber optic determination and the geophysical use of gravity. Additional information on these and other methods may be found in Dane and Topp (2002), Baker (1990), Campbell and Mulla (1990), Carter (1993), and Robinson et al. (2008a).

4.2.3 Applications of Soil Water Content Information

4.2.3.1 The Water Balance

A primary use of soil water content information is for evaluation of the hydrologic water balance described by

$$P + I = ET + D + R - \Delta W, \quad (4.15)$$

where

P is precipitation

I is irrigation

ET is evapotranspiration (evaporative water loss from the soil and from plants)

D is drainage or deep percolation

R is surface runoff

ΔW is change in water storage within the profile (soil water depletion)
FIGURE 4.7 Schematic of soil water depletion calculations for a soil profile divided into four depth increments. Total change in water storage is the sum of depletion in each layer.

W is defined as the equivalent depth of water (D_e) stored in the soil profile under consideration and $\Delta W = (W_{initial} - W_{final})$ (Figure 4.7). These parameters are all associated with a given specific time interval. The convention used here is that inputs to the soil profile are taken as positive and outputs negative. The concept is based on conservation of mass (water) and is similar to the familiar exercise of balancing inputs and outgoings from a checking account, for example. Under typical conditions, ΔW is fairly significant over the short term (weeks to months), but generally evens out to about zero over one to several years. Measurement of water content for water balance studies requires the determination of profile soil moisture. An international study (IAEA, 2008) found that the neutron probe remains the most accurate and precise method for the determination of profile soil water content in a range of soil types. Of the sensors tested, they found that conventional TDR and the neutron probe method were the only indirect methods to have acceptable accuracy for field water balance studies.

4.2.3.2 Field Capacity, Wilting Point, and Plant-Available Soil Water

Observations of water content changes in the soil profile following wetting by irrigation or rainfall show that the rate of change decreases in time. In some cases, water content attains a nearly constant value within 1–2 days after wetting, following soil water redistribution in response to internal drainage. Field capacity is defined as the water content at which internal drainage becomes essentially negligible. The attainment of a near constant water content at field capacity (θ_{vFC}) is not always assured. It is dependent on (1) the depth of wetting and the antecedent (initial) water content of the soil profile (for a soil that is moist at the onset of wetting and for deep wetting, the rate of redistribution is slower and the apparent value of θ_{vFC} is higher) and (2) the

presence of impeding layers or a water table, which affect the rate and extent of water redistribution.

Another often misunderstood soil water content-related index is the permanent wilting point, which is defined as the water content at which plants can no longer extract soil water at a rate sufficient to meet physiological demands imposed by loss of water to the atmosphere, and thus irreversibly wilt and die. This water content (θ_{vWP}) is primarily dependent on the soil's ability to transmit water, but also to some degree on the plant's ability to withstand or mitigate drought. Though commonly taken as θ_v at −1.5 MPa (−15 bars) matric potential, there is substantial variation among plant species in their abilities and mechanisms to resist soil drought, with some plants, such as dryland shrubs and trees, surviving to potentials of approximately −8 MPa, well below the standard wilting point index. The permanent wilting point should not be confused with the phenomenon of transient wilting, which is commonly observed during the afternoon when evaporative demand is greatest. In this case, plants are able to rehydrate to some extent at night.

A primary practical use of field capacity and wilting point concepts is the determination of a plant-available soil water range (PASW; Figure 4.8). Soil water storage available for plant use is generally calculated as being between field capacity and wilting point ($\theta_{vFC} - \theta_{vWP}$), as water contents higher than θ_{vFC}, while usually plant-available, are generally not sustained for long periods of time except under specific circumstances. Plant-available soil water storage is an important factor in the determination of irrigation amounts for a cropped field or other soil–plant system. For practical purposes, irrigation amounts in excess of field capacity are lost to deep percolation, and thus, should be avoided in the interests of water resource efficiency as well as potential leaching of soluble chemicals (Chapter 7).

A useful rule of thumb is to estimate θ_{FC} as $\theta_s/2$, and θ_{WP} as $\theta_{FC}/2$; in other words, a soil exhibiting this property would
FIGURE 4.8 Schematic of estimated PASW content for a range of soil textural classes.

have lost 50% of its saturated water content at field capacity, and another 50% of the remaining water by the wilting point. Richards (1954) was probably the first to make this observation. Banin and Amiel (1970) and Dahiya et al. (1988) have also demonstrated that the assumed ratio is a good approximation, based on measured correlations on many soils.

4.2.3.3 Sources of Additional Information on Soil Water Content Indices

The information on these indices is fragmentary due to their dependency on other conditions in the soil profile (field capacity) and the plant in question (wilting point). The work of Slater and Williams (1965) provides a reasonable framework for estimating field capacity, and more recent information may be found on the Internet. A study by Waters (1980) is a good source of information regarding the wilting point. Dahiya et al. (1988) presented strong correlations among the saturation percentage, field capacity, wilting point, and available water based on data for 438 soils, with correlation coefficients in excess of 0.92. Banin and Amiel (1970) provided similar information concerning relationships among clay content, surface area, and water content at several index points. Petersen et al. (1996) also related soil surface area and other properties to their water-holding capacity.

4.2.3.4 The Role of Soil Moisture in Hydrology, Biogeochemistry, and Ecology

Soil moisture plays a critical role across a range of scales within hydrology. Entekhabi et al. (1996) demonstrated the mutual interaction between soil moisture states and atmospheric processes. Soil moisture becomes an important source of atmospheric water at continental scales, a fraction of which falls as precipitation back on the land surface downwind from the site of the original evapotranspiration. Soil moisture also plays an important role in determining the albedo of soils (Idso et al., 1974), this has become increasingly important in the global energy balance, as land-use change has occurred and more soils are cultivated and urbanization expands. At the watershed scale, the antecedent moisture conditions play a critical role in determining if rainfall will infiltrate or runoff, especially where saturation excess runoff processes dominate (Dunne and Black, 1970). As a result, significant effort has been placed on trying to determine water content across small watersheds (Grayson et al., 1997; Western and Grayson, 1998; Western et al., 1999).

Biogeochemical cycling describes the transformation of elements from one form to another. Soil moisture has been recognized from early in the history of soil science as a controlling factor over rates of weathering and soil formation (Jenny, 1941). In addition to controlling some weathering processes, such as hydrolysis and hydration, which are important for the release of nutrients, for example, phosphorus, perhaps more importantly moisture controls microbial activity in soils (Skopp et al., 1990). The microbial activity is the powerhouse behind many soil processes, for instance, nitrification and the evolution of CO_2 from microbial respiration (Stanford and Epstein, 1974; Schjonning et al., 2003; Turcu et al., 2005).

Ecohydrology has emerged as a distinct subdiscipline within hydrology and focuses in part on soil moisture (Rodriguez-Iturbe and Porporato, 2005). However, ecologists have been studying soil moisture and soil temperature for many years with regard to their role in determining plant community spatial organization and net primary productivity (Pastor and Post, 1986). Soil moisture provides the reservoir of water for plant growth and determining the available pool of water and its functionality is seen as increasingly critical in explaining and predicting vegetation response in drier climates (Ryel et al., 2008).

4.3 Soil Water Energy

As previously stated, water status in soils is characterized by both the amount of water present and by its energy state. Soil water is subjected to forces of variable origin and intensity, thereby acquiring different quantities and forms of energy. The two primary forms of energy of interest here are kinetic and potential. Kinetic energy is acquired by virtue of motion and is proportional to velocity squared. However, because the movement of water in soils is relatively slow (usually <0.1 m h^{-1}), its kinetic energy is negligible. The potential energy, which is defined by the position of soil water within a soil body and by internal conditions, is largely responsible for determining soil water status under isothermal conditions.

Like all other matter, soil water tends to move from where the potential energy is high to where it is low, in its pursuit of a state known as equilibrium with its surroundings. The magnitude of the driving force behind such spontaneous motion is a difference in potential energy across a distance between two points of interest. At a macroscopic scale, one can define potential energy relative to a reference state. The standard state for soil water is defined as pure and free water (no solutes and no external forces other than gravity) at a reference pressure, temperature, and elevation, and is arbitrarily given the value of zero (Bolt, 1976).

4.3.1 Total Soil Water Potential and Its Components

Soil water is subject to several force fields whose combined effects result in a deviation in potential energy relative to the reference state called the total soil water potential (ψ_T) and is defined as follows:

The amount of work that an infinitesimal unit quantity of water at equilibrium is capable of doing when it moves (isothermally and reversibly) to a pool of water at similar standard (reference) state (similar pressure, elevation, temperature, and chemical composition).

It should be emphasized, however, that there are alternative definitions of soil water potential using concepts of chemical potential or specific free energy of the chemical species in water (which is different than the soil solution, termed soil water here). Some of the arguments concerning the proper

definitions and their scales of application are presented by Corey and Klute (1985), Iwata et al. (1988), and Nitao and Bear (1996). Recognizing that these fundamental concepts are subject to ongoing debate, only simple and widely accepted definitions of these quantities, which are applicable at macroscopic scales and which yield an appropriate framework for practical applications, will be presented.

The primary forces acting on soil water held within a rigid soil under isothermal conditions can be conveniently grouped as (Day et al., 1967) (1) matric forces resulting from interactions of the solid phase with the liquid and gaseous phases, (2) osmotic forces owing to differences in chemical composition of the soil solution, and (3) body forces induced by gravitational and other inertial force fields (centrifugal).

The thermodynamic approach whereby potential energy rather than forces are used is particularly useful for equilibrium and flow considerations. Equilibrium would require the vector sum of these different forces acting on a body of water in different directions to be zero; this is an extremely difficult criterion to deal with in soils. On the other hand, potential energy defined as the negative integral of the force over the path taken by an infinitesimal amount of water, when it moves from a reference location to the point under consideration, is a scalar quantity. Consequently, the total potential can be expressed as the algebraic sum of the component potentials corresponding to the different fields acting on soil water:

$$\psi_T = \psi_m + \psi_s + \psi_p + \psi_z. \tag{4.16}$$

ψ_m is the matric potential resulting from the combined effects of capillarity and adsorptive forces within the soil matrix. Dominating mechanisms for these effects include (1) adhesion of water molecules to solid surfaces due to short-range London–van der Waals forces and extension of these effects by cohesion through H bonds formed in the liquid, (2) capillarity caused by liquid–gas (LG) and liquid–solid–gas interfaces interacting within the irregular geometry of soil pores, and (3) ion hydration and binding of water in diffuse double layers. There is some disagreement regarding the definition of this component of the total potential. Some consider all contributions other than gravity and solute interactions (at a reference atmospheric pressure). Others use a tensiometer (Section 4.3.4) to measure and provide a practical definition of the matric potential in a soil volume of interest (Hanks, 1992). The value of ψ_m ranges from zero when the soil is saturated to negative numbers when the soil is dry (note that $\psi_m = 0$ mm is $>\psi_m = -1000$ mm). Because it is often more convenient or intuitive to work with positive than negative quantities, the term matric suction or tension is commonly used. Each of these represents the absolute value of ψ_m.

ψ_s is the solute or osmotic potential determined by the presence of solutes in soil water, which lower its potential energy and its vapor pressure. The effects of ψ_s are important in the presence of (1) appreciable amounts of solutes and (2) a selectively permeable membrane or a diffusion barrier, which transmits water more readily than salts. The effects of ψ_s are otherwise negligible when only liquid water flow is considered and no diffusion barrier exists. The two most important diffusion barriers in the soil are (1) soil–plant root interfaces (cell membranes are selectively permeable) and (2) soil water–air interfaces; thus, when water evaporates, salts are left behind. In dilute solutions, the solute potential (also called the osmotic pressure) is proportional to the concentration and temperature according to

$$\psi_s = -RTC_s, \tag{4.17}$$

where

ψ_s is in kPa
R is the universal gas constant (8.314×10^{-3} kPa m^3 mol^{-1} K^{-1})
T is the absolute temperature (K)
C_s is solute concentration (mol m^{-3})

A useful approximation, which may be used to estimate ψ_s in kPa from the ECa of the soil solution at saturation (EC$_s$) in dS m^{-1}, is

$$\psi_s = -36EC_s. \tag{4.18}$$

ψ_p is pressure potential defined as the hydrostatic pressure exerted by unsupported water (i.e., saturating the soil) overlying a point of interest. Using units of energy per unit weight provides a simple and practical definition of ψ_p as the vertical distance from the point of interest to the overlying free water surface (unconfined water table elevation). The convention used here is that ψ_p is always positive below a water table or zero if the point of interest is at or above the water table. In this sense, nonzero magnitudes of ψ_p and ψ_m are mutually exclusive; either ψ_p is positive and ψ_m is zero (saturated conditions) or ψ_m is negative and ψ_p is zero (unsaturated conditions), or $\psi_p = \psi_m = 0$ at the free water table elevation. Another definition that is used in some quarters is to combine ψ_m and ψ_p as used here into a single component that adopts negative magnitude under unsaturated conditions and positive magnitude under saturated conditions.

ψ_z is gravitational potential, which is determined solely by the elevation of a point relative to some arbitrary reference point and is equal to the work needed to raise a body against the earth's gravitational pull from a reference level to its present position. When expressed as energy per unit weight, the gravitational potential is simply the vertical distance from a reference level to the point of interest. The numerical value of ψ_z itself is thus not important (it is defined with respect to an arbitrary reference level); what is important is the difference or gradient in ψ_z between any two points of interest. This value will not change with different reference point locations.

Soil water is at equilibrium when the net force on an infinitesimal body of water equals zero everywhere, or when the total potential is constant in the system. Though the last statement is a logical consequence of the definitions above, it is not strictly true as pointed out by Corey and Klute (1985). They argue that

constant total potential is a necessary but not a sufficient condition, and for thermodynamic equilibrium to prevail, three conditions must be met simultaneously: (1) thermal equilibrium or uniform temperature, (2) mechanical equilibrium meaning no net convection producing force, and (3) chemical equilibrium meaning no net diffusional transport or chemical reaction. In most practical applications, however, the macroscopic definition of the total potential and equilibrium conditions based on it is completely adequate (Kutilek and Nielsen, 1994).

The difference in chemical and mechanical potentials between soil water and pure water at the same temperature is known as the soil water potential (ψ_w):

$$\psi_w = \psi_m + \psi_s + \psi_p. \qquad (4.19)$$

Note that the gravitational component (ψ_z) is absent in this definition. Soil water potential is thus the result of inherent properties of soil water itself, and of its physical and chemical interactions with its surroundings, whereas the total potential includes the effects of gravity (an external and ubiquitous force field).

Total soil water potential and its components may be expressed in several ways depending on the definition of a unit quantity of water. Potential may be expressed as (1) energy per unit of mass, (2) energy per unit of volume, or (3) energy per unit of weight. A summary of the resulting dimensions, common symbols, and units are presented in Table 4.1.

Only μ has actual units of potential; ψ has units of pressure, and the units of h are in head of water (length). However, the above terminology (potential energy vs. units of potential) is widely used in a generic sense in the soil and plant sciences. The various expressions of soil water energy status are equivalent, with

$$\mu = \psi/\rho_w = gh, \qquad (4.20)$$

where
  ρ_w is density of water (1000 kg m^{-3} at 20°C)
  g is gravitational acceleration (9.81 m s^{-2})

4.3.2 Interfacial Forces and Capillarity

The matric potential is often the largest component of the total potential in partially saturated soils. To better understand the origins of this important potential, which attains nonzero values only under partial saturation when all the three phases (liquid, gas, and solid) are present, some of the properties of water in relation to porous media, which give rise to this phenomenon, must be discussed.

4.3.2.1 Surface Tension

At the interface between water and solids or other fluids such as air, water molecules are exposed to different forces than are molecules within the bulk water. For example, water molecules inside the liquid are attracted by equal cohesive forces to form H bonds on all sides, whereas molecules at the air–water interface feel a net attraction into the liquid because the density of water molecules on the air side of the interface is much lower and all H bonds are toward the liquid. The result is a membrane-like water surface having a tendency to contract; thus energy is stored in the form of surface tension (as in a stretched spring). Different liquids vary in their LG surface tension (σ_{LG}) expressed as energy per unit area = force per unit length. For example, water at 20°C: 72.7 mN m^{-1} = mJ m^{-2}; ethyl alcohol: 22 mN m^{-1} (=dyn cm^{-1} = erg cm^{-2}); and mercury: 430 mN m^{-1}.

4.3.2.2 Contact Angle

If liquid is placed in contact with a solid in the presence of a gas (three-phase system), the angle measured from the solid–liquid (SL) interface to the LG interface is the contact angle (γ). For a drop resting on a solid surface at equilibrium, the vector sum of the forces acting to spread the drop (outward) is equal to the opposing forces. This relationship is summarized by Young's equation (Adamson, 1990):

$$\sigma_{LG} \cos\gamma + \sigma_{SL} - \sigma_{GS} = 0, \qquad (4.21)$$

where σ is the respective interfacial surface tension. The equilibrium contact angle is therefore

$$\gamma = \cos^{-1}\left[\frac{\sigma_{GS} - \sigma_{SL}}{\sigma_{LG}}\right]. \qquad (4.22)$$

When liquid is more attracted to the solid (adhesion) than to other liquid molecules (cohesion), the angle is small and the solid is said to be wettable by the liquid. Conversely, when the cohesive exceeds the adhesive force, the liquid repels the solid and γ is large (Figure 4.9). The contact angle of water on clean glass is very small and is commonly taken as 0°. The contact

TABLE 4.1 Units, Dimensions, and Common Symbols for Potential Energy of Soil Water

Units	Symbol	Name	Dimensions	SI Units	cgs Units
Energy/mass	μ	Chemical potential	$L^2 t^{-2}$	J kg^{-1}	erg g^{-1}
Energy/volume	Ψ	Soil water potential, suction, or tension	$M (L t^2)^{-1}$	N m^{-2} (Pa)	erg cm^{-1}
Energy/weight	h	Pressure head	L	m	cm
FIGURE 4.9 Liquid–solid–gas contact angles for (a) a small angle where the liquid wets the solid and (b) a large angle in which the liquid is repelled by the solid surface.

angle of soil water on soil minerals is also commonly assumed ~0°. The different contact angles of water and other liquids with soil solids, soil air, and with each other, are important contributors to the behavior of multiphase organic liquid/water/soil/air mixtures.

4.3.2.3 Curved Surfaces and Capillarity

Surface tension is associated with the phenomenon of capillarity. When the LG interface is curved rather than planar (flat), the resultant surface tension force normal to the LG interface creates a pressure difference across the interface. The pressure is greater at the concave side of the interface by an amount that is dependent on the radius of curvature and the surface tension of the fluid. For a hemispherical LG interface having radius of curvature R, the pressure difference is given by the Young–Laplace equation:

$$\Delta P = 2\sigma/R, \tag{4.23}$$

where

$\Delta P = P_{liq} - P_{gas}$ when the interface curves into the gas (water droplet in air)

$\Delta P = P_{gas} - P_{liq}$ when the interface curves into the liquid (air bubble in water, water in a small glass tube)

In many instances, a bubble may not be spherical or an element of liquid may be confined by irregular solid surfaces resulting in two (or more) different radii of curvature such as water in pendular rings between two spherical solid particles (Figure 4.10). The Young–Laplace equation for this case is given by:

$$\Delta P = \sigma\left(\frac{1}{R_1} + \frac{1}{R_2}\right). \tag{4.24}$$

Note that (1) this equation reduces to Equation 4.23 for $R_1 = R_2$ and (2) the sign of R_i is negative for convex interfaces ($R_2 < 0$) and positive for concave interfaces ($R_1 > 0$).
FIGURE 4.10 Radii of curvature for pendular ring of water between two spherical solids.

4.3.3 The Capillary Model

4.3.3.1 Capillary Rise

When a small cylindrical glass tube (capillary) is dipped in free water, a meniscus is formed as a result of the contact angle between the water and the walls of the tube and from consideration of minimum surface energy. The smaller the tube the larger the degree of curvature, resulting in a larger pressure difference across the air–water (gas–liquid) interface. The pressure at the water side (P_W) will be lower than atmospheric pressure (P_0). This pressure difference will cause water to rise into the capillary tube until the upward force across the water–air interface is balanced by the weight of water in the tube (Figure 4.11). Because the radius of meniscus curvature R = r/cos γ, where r is the tube radius, the height that water will rise in a capillary tube of radius r with γ contact angle is

$$h = \frac{2\sigma \cos \gamma}{\rho_w g r}. \tag{4.25}$$

Combining all the constants in Equation 4.25 (using typical values at room temperature) yields a simple and useful approximation:

$$h(m) = \frac{14.84}{r(\mu m)}. \tag{4.26}$$

When expressed as potential energy per unit weight, $\psi_m = -h$ and thus may be related to equivalent pore radius through Equation 4.25.
FIGURE 4.11 Capillary rise in cylindrical glass tubes.

4.3.3.2 Conceptual Models for Water in Soil Pore Space

The complex geometry of soil pore space creates numerous combinations of interfaces, capillaries, and wedges around which films of water are formed, resulting in a variety of air–water and solid–water contact angles. Water is thus drawn into and/or held by these interstices in proportion to the resulting capillary forces. In addition, water is adsorbed onto solid surfaces with considerable force at close distances. Due to practical limitations of the present measurement methods, no distinction is made between the various mechanisms affecting water in porous matrices (i.e., capillarity and surface adsorption). Common conceptual models for water retention in porous media and matric potential rely on a simplified picture of soil pore space as a bundle of capillaries. The primary conceptual steps made in such models are illustrated in Figure 4.12. The representation of soil pores as equivalent cylindrical capillaries greatly simplifies modeling and parameterization of soil pore space. The roles of water films at very low saturation levels and the unique contribution of surface adsorption to the matric potential are beyond the scope of this chapter. Interested readers are referred to reviews by Nitao and Bear (1996) and Parker (1986).

4.3.4 Measurement of Soil Water Potential Components

4.3.4.1 Tensiometer for Measuring Soil Matric Potential

A tensiometer consists of a porous cup, usually made of ceramic having very fine pores, connected to a vacuum gauge through a water-filled tube (Figure 4.13). The porous cup is placed in intimate contact with the bulk soil at the depth of measurement. When the matric potential of the soil is lower (more negative) than the equivalent pressure inside the tensiometer cup, water
FIGURE 4.12 Concept of equivalent cylindrical capillary to represent soil pore spaces.

moves from the tensiometer along a potential energy gradient to the soil through the saturated porous cup, thereby creating suction sensed by the gauge. Water flow into the soil continues until equilibrium is reached and the suction inside the tensiometer equals the soil matric potential. When the soil is wetted, flow may occur in the reverse direction, that is, soil water enters the tensiometer until a new equilibrium is attained. The tensiometer equation is

$$\psi_m = \psi_{gauge} + (z_{gauge} - z_{cup}). \tag{4.27}$$

The vertical distance from the gauge plane (z_{gauge}) to the cup (z_{cup}) must be added to the matric potential measured by the gauge (expressed as a negative quantity) to obtain the matric potential at the depth of the cup, when potentials are expressed per unit of weight. This accounts for the positive head at the depth of the ceramic cup exerted by the overlying tensiometer water column.

Electronic sensors called pressure transducers often replace the mechanical vacuum gauges. The transducers convert mechanical pressure into an electric signal, which can be more easily and precisely measured. In practice, pressure transducers can provide more accurate readings than other gauges, and in combination with data logging equipment are able to supply continuous measurements of soil matric potential. Portable tensiometers that may be extended into boreholes for use at depths to several hundred meters have also been developed (Hubbell and Sisson, 1996). Achieving and maintaining adequate hydraulic contact between the porous cup and the soil at these depths was identified as an important issue, but these sensors may be highly useful in some mining, engineering, deep recharge, and hazardous waste applications.
FIGURE 4.13   Pressure transducer and vacuum gauge tensiometers showing porous ceramic cup.

The standard tensiometer range is limited to suction values (absolute value of the matric potential) <100 kPa (1 bar or 10 m head of water) at sea level, and this value decreases proportionally with elevation. Thus, other means are needed to measure or infer soil matric potential under drier conditions.

Peck and Rabbidge (1969) described an osmotic tensiometer that relied on a confined aqueous solution behind a semipermeable membrane, rather than using free water as the reference state. A membrane highly impermeable to the confined solution allowed their device to cover the entire range of 0 to −1.5 MPa, unless soil solutes were excluded from the instrument by a vapor gap. Following the design of these osmotic tensiometers, polymer tensiometers have been developed, which utilize synthetic polymers (i.e., polyethylene glycol, polyacrylamide, and polyvinylpyrrolidone) in place of solutes to fill a small reservoir connected to the pressure transducer (Bakker et al., 2007). Keys to successful operation include reduction of thermal sensitivity, the prevention of polymer degradation or leakage from the reservoir using a secondary membrane, and maintenance of soil–ceramic contact for hydraulic continuity at low potentials.

4.3.4.2 Piezometer for Measuring Hydrostatic Pressure Potential

In a saturated soil such as below a water table, soil water is under positive hydrostatic pressure. The pressure potential (ψ_p) equals the vertical distance from a point in the soil to the surface of the free water table (recall that one expresses potential in terms of distance, length, or head when potential energy is expressed per unit of weight). The piezometer is a hollow tube placed in the soil to depths below the water table. It extends to the soil surface and is open to the atmosphere. The bottom of the piezometer is perforated to allow for soil water under positive hydrostatic pressure to enter the tube. Water enters the tube and rises to a height equal to that of the free water table. The water level within the piezometer may be determined using a variety of manual or automated measurement techniques.

4.3.4.3 Water Vapor Pressure for Measuring Water Potential

Under equilibrium conditions, the soil water potential is equal to the potential of water vapor in the surrounding soil air. A psychrometer measures the relative humidity (RH) of the water vapor, which is related to the water potential of the vapor (ψ_w) through the Kelvin equation:

$$\text{RH} = e/e_o = \exp^{[(M_w\psi_w)/(\rho_w RT)]}, \tag{4.28}$$

where
  e is water vapor pressure
  e_o is saturated vapor pressure at the same temperature
  M_w is the molecular weight of water (0.018 kg mol^{-1})
  R is the ideal gas constant (8.31 J K^{-1} mol^{-1} or 0.008314 kPa m^3 mol^{-1} K^{-1})
  T is absolute temperature (K)
  ρ_w is the density of water (1000 kg m^{-3} at 20°C)

Rearranging and taking a log transformation of Equation 4.28 yields

$$\psi_w = \frac{RT\rho_w}{M_w}\ln(e/e_o). \quad (4.29)$$

Equation 4.29 can be further simplified for the range of e/e_o near 1 often encountered in soils (the entire range of plant-available water is between $e/e_o = 1$ and 0.98):

$$\psi_w = \frac{RT\rho_w}{M_w}\left(\frac{e}{e_o} - 1\right) \approx 462\,T\left(\frac{e}{e_o} - 1\right), \quad (4.30)$$

for ψ_w in kPa. Note that because most salts are nonvolatile, the psychrometric measurement of ψ_w is the sum of the osmotic and matric potentials ($\psi_w = \psi_m + \psi_s$). The soil–air interface acts as a diffusion barrier in allowing only water molecules to pass from liquid to vapor state.

Understanding measurements of soil water potential using a determination of the soil air-phase humidity can be enhanced by a psychrometric chart because one can observe relationships among the different measurement techniques. A psychrometric chart depicts the physical properties of moist air computed for a fixed pressure or elevation. Thermophysical properties depicted in the chart may include dry-bulb and wet-bulb temperature, dew point temperature, vapor pressure, RH, humidity ratio, specific enthalpy, and specific volume (inverse air density). Measurements commonly carried out in soil access dry- and wet-bulb temperature using thermocouple psychrometry or dew point temperature using chilled mirror techniques, where matric potential is often related to the soil vapor pressure. In the following, we briefly describe the psychrometric chart and the interrelations among different thermophysical properties and then review the associated measurement techniques.

The psychrometric chart depicted in Figure 4.14 requires a pair of known or measured values in order to determine the unknown properties for a given condition. Typically dry-bulb (air) temperature is measured along with wet-bulb temperature. For example, assuming a thermocouple psychrometer measured a dry-bulb temperature of 25°C and a wet-bulb temperature of 23°C, the resulting RH according to this chart is 85%. This value is computed from the ratio of the vapor pressure to the saturation vapor pressure at 25°C, which are 20.2 and 24.8 mm Hg, respectively. The corresponding dew point temperature is observed to be 22.1°C.

4.3.4.4 Psychrometry for Measuring Soil Water Potential

A psychrometer measures the difference between dry-bulb and wet-bulb temperatures to determine the RH. The dry

FIGURE 4.14 Psychrometric chart showing relationships between dry-bulb (T_{db}), wet-bulb (T_{wb}), and dew point (T_{dp}) temperatures in addition to water vapor pressure (e) and saturation vapor pressure (e_o) for an elevation of 1500 m (85 kPa). In this example, a psychrometer measures dry-bulb (T_{db}) and wet-bulb (T_{wb}) temperatures of 25°C and 23°C, respectively, indicating a RH of 85%. From the chart, a corresponding dew point temperature (T_{dp}) is 22.1°C and the vapor pressure of 20.2 mm Hg and a saturation vapor pressure of 24.8 mm Hg (note: RH = e/e_o).

bulb is the temperature of the ambient air (nonevaporating surface), and the wet bulb is the temperature of an evaporating surface (generally lower than the dry-bulb temperature). The RH determines the rate of evaporation from the wet-bulb junction, and thus the extent of temperature depression below ambient.

A thermocouple psychrometer consists of a fine-wire chromel–constantan or other bimetallic thermocouple. A thermocouple is a double junction of two dissimilar metals. When the two junctions are subjected to different temperatures, they generate a voltage difference (Seebeck effect). Conversely, when an electrical current is applied through the junctions, it creates a temperature difference between the junctions by heating one while cooling the other, depending on the current's direction. For typical soil use, one junction of the thermocouple psychrometer is suspended in a thin-walled porous ceramic or stainless screen cup buried in the soil (Figure 4.15a), while another is embedded in an insulated plug to measure the ambient temperature at the same location. In psychrometric mode, the suspended thermocouple is cooled below the dew point by means of an electrical current (Peltier cooling) until pure water condenses on the junction. The cooling current then stops, and as water evaporates, it draws heat from the junction (heat of vaporization), depressing it below the temperature of the surrounding air until it attains a wet-bulb temperature. The warmer and drier the surrounding air, the higher the evaporation rate and the greater the wet-bulb depression. The difference in temperatures between the dry- and wet-bulb thermocouples

is measured and used to infer the RH (or relative vapor pressure) using the psychrometer equation:

$$\frac{e}{e_o} = 1 - \left[\frac{s + \gamma}{e_o}\right]\Delta T, \qquad (4.31)$$

where

s is the slope of the saturation water vapor pressure curve ($s = de_o/dT$)

γ is the psychrometric constant (about 0.067 kPa K^{-1} at 20°C)

ΔT is the temperature difference (K)

The slope (s) and e_o are functions of temperature only and can be approximated by closed-form expressions (Brutsaert, 1982).

A typical temperature depression measurable by a good psychrometer is on the order of 0.000085 C kPa^{-1}. This means that any errors in measuring wet-bulb depression can introduce large errors into psychrometric determinations. Thermal equilibrium is, therefore, a prerequisite to obtaining reliable readings, as any temperature difference between wet and dry sensors resulting from thermal gradients will be (erroneously) incorporated into the RH calculation.

Summarizing, psychrometric measurements of soil water potential are based on equilibrium between liquid soil water and water vapor in the ambient soil atmosphere. The drier the soil, the fewer water molecules escape into the ambient atmosphere resulting in lower RH (lower vapor pressure). When the

osmotic potential is negligible, the soil water potential measured by a psychrometer is nearly equal to the soil matric potential. In principle, soil psychrometers may be buried in the soil and left for long periods, although corrosion is a problem in some environments.

4.3.4.5 Dew Point Potentiometer for Measuring Soil Water Potential

In a cooling process, the temperature at which water vapor condenses into water is known as the dew point temperature (T_{dp}) and occurs near 100% RH. This temperature is illustrated in Figure 4.15b, where T_{dp} is 22.1°C corresponding with the dry- and wet-bulb temperature intersection point in the previous example. Note that the dew point temperature is also found by drawing a horizontal line to the left intersecting the 100% humidity curve and dropping vertically to the corresponding air (dry bulb) temperature. In Figure 4.15b, a detailed measurement system from a Decagon WP4-T illustrates the electronics and hardware, which measure the soil water potential using the chilled mirror dew point technique.

4.3.4.6 Reference Porous Matrix Properties for Measuring Matric Potential

The interdependence of soil matric potential and water content facilitates indirect methods for inferring the energy of soil water from water content-dependent physical property measurements where a well-characterized and repeatable porous matrix can be produced. Measurement approaches have included thermal, electrical, dielectric measurements within porous media including plaster of Paris, ceramics, fiberglass, porous plastics, and natural soils (Wraith and Or, 2001). The measurable physical property (heat capacity, thermal conductivity, electrical resistivity, dielectric constant) of a porous matrix is affected by its water content and hence related to its matric potential. With the reference matrix sensor buried in the soil, changes in soil matric potential result in a gradient between the soil and the reference matrix that induces a water flux between the two materials until a new equilibrium potential is established. Reference matrix sensor physical properties being measured are influenced by these water content changes. In this manner, the measured sensor response yields quasi-direct information on the soil matric potential and indirect information on soil wetness where a water retention relationship is known. A common challenge of these sensors is quality mass production of the reference porous medium whose θ–ψ relationship exhibits low variance and whose hydraulic properties are compatible with the soil being measured. Accuracy, repeatability, and spatial resolution of specific sensors or methods are important considerations to their potential applications and in the analysis of soil matric potential measurements.

Heat dissipation sensors contain line- or point-source heating elements embedded in a rigid porous matrix with fixed pore space. The measurement is based on applying a heat pulse by passing a constant current through the heating element for a specified time and analyzing the temperature response

measured by a thermocouple fixed at a known distance from the heating source (Phene et al., 1971; Bristow et al., 1993). Sensors are individually or uniformly calibrated in terms of heat dissipation versus sensor wetness (i.e., matric potential). A typical useful matric potential range for such sensors is −10 to −1000 kPa.

A similar line-source sensor with a fine-wire heating element axially centered in a cylindrical ceramic matrix having a radius of 1.5 cm and length of 4.2 cm is depicted in Figure 4.16. A thermocouple is located adjacent to the heating element at mid-length. Both the heating wire and the thermocouple are contained in the shaft portion of a hollow needle. Because the thermocouple is located adjacent to the heating element, as the soil dries and water moves out of the ceramic, the magnitude of temperature change during a given period under constant heating current and duration will increase due to the reduced thermal conductivity of the porous matrix. The magnitude of the measured temperature increase and/or decrease is often linearly related to the natural logarithm of matric potential. The accuracy and operational limits of these sensors were evaluated by Reece (1996), who also presented an improved calibration method for between-sensor variability, based on normalizing sensor readings by oven dry sensor thermal conductivity. A primary advantage of these sensors is their wide range of applicability from about −0.1 to −12.0 MPa.

Electrical resistance sensors have been used in soils for matric potential determination since the work of Bouyoucos and Mick (1940) and continue to be developed to this day. Ongoing efforts seek to overcome limitations associated with temperature and salinity dependence on the resistance measurement (see Section 4.2.2.7). The measurement method is popular because sensors are inexpensive to produce. Measuring the dielectric of a reference porous medium can be used to infer soil matric potential. Early studies used TDR probes embedded in plaster of Paris or ceramic with a well-characterized θ–ψ relationship in the range of −30 to −1000 kPa (Noborio et al., 1999). Commercially available dielectric-based sensors provide a narrower measurement range of −10 to −500 kPa but are less expensive to produce. Some limitations of this method include possible effects from salinity
FIGURE 4.16 Schematic of CSI 229 heat dissipation sensor. (From Campbell Scientific, Inc., Logan, UT.)

on the dielectric measurement, especially at measurement frequencies below 100 MHz, and an altered $\theta-\kappa$ relationship occurring in frozen soils.

4.4 Soil Water Content—Energy Relationships

4.4.1 Soil Water Characteristic

An SWC curve describes the functional relationship between soil water content (θ_m or θ_v) and matric potential under equilibrium conditions. The SWC is an important soil property related to the distribution of pore space (sizes, interconnectedness), which is strongly affected by texture and structure, as well as related factors including organic matter content. The SWC is a primary hydraulic property required for modeling water flow, for irrigation management, and for many additional applications related to managing or predicting water behavior in the porous system. An SWC is a highly nonlinear function and is relatively difficult to obtain accurately. Because the matric potential extends over several orders of magnitude for the range of water contents commonly encountered in practical applications, the matric potential is often plotted on a logarithmic scale. Several SWC curves for soils of different textures demonstrating the effects on porosity (saturated water content) and on the slope of the relationships resulting from variable pore-size distributions are depicted in Figure 4.17.

4.4.2 Measurement of SWC Relationships

Several methods are available to obtain the measurements needed for SWC estimation. The basic requirement is for pairs of $\psi_m-\theta$ measurements over the wetness range of interest. Among the primary experimental problems in determining an SWC are (1) the limited functional range of the tensiometer, which is often used for in situ measurements, (2) inaccurate θ measurements in

some cases, (3) the difficulty in obtaining undisturbed samples for laboratory determinations, and (4) a slow rate of equilibrium under low matric potential (i.e., dry soils).

In situ methods are considered the most representative for determining SWCs, particularly when a wide range of $\psi_m-\theta_v$ values are obtained. An effective method to obtain simultaneous measurements of ψ_m and θ_v utilizes TDR probes installed in the soil at close proximity to transducer tensiometers and/or other matric sensors, with the changing values of each attribute monitored through time as the soil wetness varies. Large changes in ψ_m and θ_v can be induced under highly evaporative conditions near the soil surface or in the presence of active plant roots.

4.4.2.1 Laboratory Estimation Using Pressure Plate and Pressure Flow Cell

The pressure plate apparatus consists of a pressure chamber enclosing a water-saturated porous plate, which allows water but prevents air flow through its pores (Figure 4.18). The porous plate is open to atmospheric pressure at the bottom, while the top surface is at the applied pressure of the chamber. Sieved soil samples (usually <2 mm) are placed in retaining rubber rings in contact with the porous plate and left to saturate in water. After saturation is attained, the porous plate with the saturated soil samples is placed in the chamber and a known gas (commonly N_2 or air) pressure is applied to force water out of the soil and through the plate. Flow continues until equilibrium between the force exerted by the air pressure and the force by which soil water is being held by the soil (ψ_m) is reached.

Soil water retention in the low suction range of 0–10 m (=1 bar = 0.1 MPa) is strongly influenced by soil structure and its natural pore-size distribution. Hence, undisturbed intact soil samples (cores) are preferred over repacked samples for the wet end of the SWC. The pressure flow cell (Tempe cell) can hold intact soil samples encased in metal rings. The operation of the cell follows that of the pressure plate, except the pressure range is usually lower (0–10 m). The porous ceramic plates for both the pressure plate and the flow cell must be completely saturated, a process which may take a few days to achieve. Following equilibrium between soil matric potential and the applied air pressure, the soil samples are removed from the apparatus, weighed, and oven dried for gravimetric determination of water content. An estimate of the soil sample bulk density must be provided to convert θ_m to θ_v in the case of disturbed samples. Because of differences in pore sizes and geometry, the water content of repacked soils at a given matric potential should not be used to accurately infer θ of intact soils at the same ψ_m.

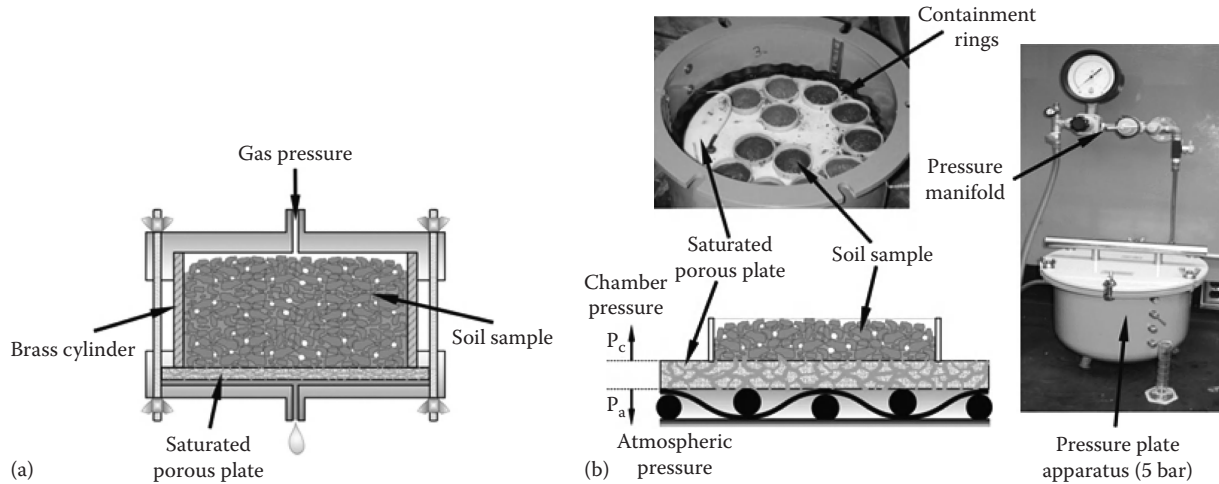
Several pressure steps may be applied to the same samples when using flow cells. The cells may be disconnected from the air pressure source and weighed to determine the change in water content from the previous step, then reconnected to the air pressure and a new (greater) pressure step applied. Water outflow from the cells may also be monitored and related by volume or mass to the change in sample water content.
FIGURE 4.17 Example of soil water retention relationships for three soil textures.


FIGURE 4.18 (a) Pressure flow cell (Tempe cell) and (b) pressure plate apparatus used to desaturate soil samples to desired matric potential.

4.4.2.2 Field Measurement Methods—Sensor Pairing

Despite the paramount importance of SWC determination in situ, suitable measurement techniques are severely lacking at present. The most common approach is to use paired sensors such as neutron moisture meter access tubes or TDR waveguides and tensiometers to determine water content and matric potential simultaneously and in the same soil volume. Single probes that combine TDR with tensiometry have also been proposed (Baumgartner et al., 1994). The limitations of most sensor pairing techniques stem from (1) differences in the soil volumes sampled by each sensor (e.g., large volume averaging by a neutron moisture meter vs. a small volume sensed by a heat dissipation sensor or a psychrometer), (2) the time required for matric potential sensors to reach equilibrium, and (3) limited ranges and deteriorating accuracy of different sensor pairs. This often results in limited overlap in SWC information measured using different techniques and problems with measurement errors within the range of overlap.

A summary of common methods available for matric potential measurement or inference and their range of application is presented in Figure 4.19. Note that most of the available techniques have a limited range of overlap (or do not overlap at all), and most are laboratory methods not suitable for field applications.

4.4.3 Fitting Parametric SWC Expressions to Measured Data

Measuring an SWC is laborious and time consuming. Measured θ–ψ pairs are often fragmentary, and usually constitute relatively few measurements over the wetness range of interest. For modeling and analysis purposes and for characterization and comparison between different soils and scenarios, it is therefore beneficial to represent the SWC in a continuous and parametric form (Fredlund and Xing, 1994). A parametric expression of an SWC model should (1) contain as few parameters as necessary to simplify its estimation and (2) describe the behavior of the SWC

FIGURE 4.19 Typical ranges of application for some common matric potential measurement or inference methods.

at the limits (wet and dry ends) while closely fitting the nonlinear shape of $\theta(\psi_m)$ data.

An effective and commonly used parametric model for relating water content to the matric potential was proposed by van Genuchten (1980) and is denoted as VG:

$$\Theta = \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left[\frac{1}{1 + (\alpha \, | \, \psi_m \, |)^n} \right]^m, \qquad (4.32)$$

where

θ_r and θ_s are the residual and saturated water contents, respectively

α, n, and m are parameters directly dependent on the shape of the $\theta(\psi)$ curve

A considerable simplification is gained by assuming that m = 1 − 1/n. Thus, the parameters required for estimation of the model are θ_r, θ_s, α, and n. θ_s is usually known and is easy to
FIGURE 4.20 VG and BC parametric models fitted to measured water retention data.

obtain experimentally with good accuracy, leaving only three unknown parameters (θ_r, α, and n) to be estimated from the experimental data in many cases. Note that θ_r may be taken as $\theta_{-1.5\,MPa}$, $\theta_{air\,dry}$, or a similar value, though it is often advantageous to use it as a fitting parameter.

Another well-known parametric model was proposed by Brooks and Corey (1964) and is denoted as BC:

$$\Theta = \frac{\theta - \theta_r}{\theta_s - \theta_r} = \left[\frac{\psi_b}{\psi_m}\right]^\lambda \quad \psi_m > \psi_b$$
$$\Theta = 1 \quad \psi_m \leq \psi_b, \tag{4.33}$$

where

ψ_b is a parameter related to the soil matric potential at air entry (subscript b represents bubbling pressure)
λ is related to the soil pore-size distribution

Matric potentials are expressed as positive quantities in both VG and BC parametric expressions.

Estimation of VG or BC parameters from experimental data requires (1) sufficient data points (at least 5–8 $\theta(\psi_m)$ pairs) and (2) a program for performing nonlinear regression. Recent versions of many computer spreadsheets provide relatively simple and effective mechanisms for performing nonlinear regression. Details of the computational steps required for fitting an SWC to experimental data using commercially available spreadsheet software are given in Wraith and Or (1998). In addition, computer programs for estimation of specific parametric models are also available such as the RETC code (van Genuchten et al., 1991).

Fitted parametric models of VG and BC to silt loam $\theta(\psi)$ data measured by Or et al. (1991) are presented in Figure 4.20. The resulting best fit parameters for the VG model are $\alpha = 0.417\,m^{-1}$; n = 1.75; $\theta_s = 0.513\,m^3\,m^{-3}$; and $\theta_r = 0.05\,m^3\,m^{-3}$ (with $r^2 = 0.99$). For the BC model, the best fit parameters are $\lambda = 0.54$; $\psi_b = 1.48\,m$; $\theta_s = 0.513\,m^3\,m^{-3}$; and $\theta_r = 0.03\,m^3\,m^{-3}$ (with $r^2 = 0.98$). Note that the most striking difference between the VG and the BC models is in the discontinuity at $\psi = \psi_b$ for BC.

The water retention character of multiporosity porous media can be described by superimposing multiple SWC curves (Durner, 1994) on measured data such as those illustrated in Figure 4.21 using the following expression.

$$\Theta = \sum_{i=1}^{k} w_i \left[\frac{1}{1 + (\alpha_i |\psi_m|)^{n_i}}\right]^{m_i}, \tag{4.34}$$

where

i is an index
k is the number of SWC curves to be fitted with weighting, w_i
FIGURE 4.21 SWC of dual-porosity aggregates (1–2 mm) mapped to a corresponding pore-size distribution using Equation 4.25.

In this stable ceramic aggregate, the large disparity between internal and external pore domains results in a four-order-of-magnitude difference in the mean pore diameters mapped using Equation 4.26. The pore-size density (psd) obtained from the slope of the SWC ($d\theta/d\psi$) is informative for surface area estimation and understanding transport phenomena. Sources of additional experimental and parametric SWC information include (1) the Unsaturated Soil Hydraulic Database (UNSODA) (Leij et al., 1996), which is a computer database compiled by the US Salinity Laboratory, which contains an exhaustive collection of retention (SWC) and unsaturated hydraulic conductivity information for soils of different textures from around the world. While the authors/compilers have attempted to provide some indices of data quality or reliability, the users are advised (as always) to use their own experience and discretion in adapting others' data to their own applications; and (2) the regression studies by McCuen et al. (1981) and Rawls and Brakensiek (1989) provide a wealth of information on the BC parameter values for many soils including estimation of the hydraulic parameters based on other, often more easily available, soil properties. These estimates may be sufficiently accurate for some applications and could be used to obtain first-order approximations.

4.4.4 Hysteresis in the Soil–Water Characteristic Relation

Water content and the potential energy of soil water are not uniquely related because the amount of water present at a given matric potential is dependent on the pore-size distribution and the properties of air–water–solid interfaces. A $\theta(\psi)$ relationship may be obtained by (1) taking an initially saturated sample and applying suction or pressure to desaturate it (desorption) or by (2) gradually wetting an initially dry soil (sorption). These two pathways produce curves that in most cases are not identical; the water content in the drying curve is higher for a given matric potential than that in the wetting branch (Figure 4.22). This is called hysteresis, defined as the phenomenon exhibited by a system in which the reaction of the system to changes is dependent upon its past reactions to change.

The hysteresis in SWC can be related to several phenomena: (1) the ink bottle effect resulting from nonuniformity in shape and sizes of interconnected pores as illustrated in Figure 4.23a; drainage is governed by the smaller pore radius r, whereas wetting is dependent on the larger radius R; (2) different liquid–solid contact angles for advancing and receding water menisci (Figure 4.23b); (3) entrapped air in a newly wetted soil (e.g., pore doublet) (Dullien, 1992); and (4) swelling and shrinking of the soil under wetting and drying, which may alter the porosity and pore-size distribution. Based on early observations of the phenomenon by Haines (1930) as well as present day theories (Mualem, 1984; Kool and Parker, 1987), the role of individual factors remains unclear and is subject to ongoing research.
FIGURE 4.22 Concept of hysteresis in soil–water characteristic relationships.
FIGURE 4.23 "Ink bottle" effect (a) and the contact angle effect (b).

4.5 Resources

A number of resources are available for readers interested in additional insight or information concerning soil water content and energy. The following suggestions are by no means inclusive but should serve augmenting and extending the discussions presented here, as well as providing a source of additional references. We advise readers to consult the references we have cited in relevant sections of the chapter, as well as various texts, monographs, and review chapters. Soil physics and related textbooks, which address soil water content and water energy include those of Childs (1969), Hanks (1992), Hillel (1998), Kirkham and Powers (1972), Kutilek and Nielsen (1994), Marshall et al. (1996), Hillel (1998), and Jury and Horton (2004). Several chapters in the monograph edited by Dane and Topp (2002), as well as that edited by Carter (1993), contain valuable information. A number

of excellent review papers or chapters are also available, including Baker (1990), Campbell and Mulla (1990), and Parker (1986).

Some Internet sites contain valuable information related to soil water content and energy. These include various individual or professional organization pages, discussion groups (e.g., the soil moisture group SOWACS), and others. However, Internet addresses tend to change rather frequently, and new sources may be added. This means it is generally more efficient to conduct keyword searches using one or more of the available search engines than to rely on potentially outdated web addresses. Extensive geospatial digital soil databases are being established such as the USDA Web Soil Survey and websites detailing worldwide resources can be found online (e.g., compendium of online soil survey), In addition, there are numerous numerical modeling tools available online, which are useful for simulating soil water dynamics (e.g., Hydrus 1-D).

Water Flow in Soils

David E. Radcliffe
University of Georgia

Jirka Šimůnek
University of California, Riverside

5.1 Introduction

Water movement in soils is a key process that affects water quantity and quality in the environment. Since the transport of solutes is closely linked with the soil water flux, any quantitative analysis of solute transport must first evaluate water fluxes into and through soil. Water typically enters the soil surface in the form of precipitation or irrigation or by means of industrial and municipal spills (Figure 5.1). Some of the rainfall or irrigation water may be intercepted by the plant canopy. If the rainfall or irrigation intensity is larger than the infiltration capacity of the soil, water will be removed by surface runoff or will accumulate at the soil surface until it evaporates back to the atmosphere or infiltrates into the soil. Part of the water that infiltrates is returned back to the atmosphere by evaporation. Water that infiltrates into the soil profile may also be taken up by plant roots and eventually returned to the atmosphere by plant transpiration. The processes of evaporation and transpiration are often combined into the single process of evapotranspiration. Only water that is not returned to the atmosphere by evapotranspiration may percolate to the deeper soil zone and eventually reach the groundwater. If the water table is close enough to the soil surface, the process of capillary rise may move water from the water table through the capillary fringe toward the root zone and the soil surface.

Water movement in soils occurs under both saturated and unsaturated conditions. Saturated conditions occur below the water table where pressure head (h) is positive and water movement is predominately horizontal, with lesser components of flow in the vertical direction. While unsaturated conditions and negative pressure heads generally predominate above the water table (in the *vadose zone*), localized zones of saturation can exist especially following precipitation or irrigation or above an impermeable zone. As a general rule, water movement in the vadose zone is vertical but can also have large lateral components.

Governing equations for water flow can be developed for either steady or transient conditions, but analytical solutions usually
FIGURE 5.1 Water flow processes in soil. (From Šimůnek, J., M. Šejna, H. Saito, M. Sakai, and M.Th. van Genuchten. 2008. The HYDRUS-1D software package for simulating the movement of water, heat, and multiple solutes in variably saturated media, Version 4.0, HYDRUS Software Series 3. Department of Environmental Sciences, University of California Riverside, Riverside, CA.)

exist only for steady conditions. Although true steady flow may occur only rarely, transient flow usually approaches steady flow at long times, and the steady flow equations help to show what factors may be important under transient conditions. Numerical methods can be used to solve transient flow problems.

In the following sections, we start with steady water flow and describe the governing equations and show several examples using analytical solutions. Then we follow with transient water flow. The governing equations and initial and boundary conditions are described along with a brief introduction to numerical methods. Then, we describe in detail the important transient flow processes: infiltration, evaporation, redistribution, transpiration, preferential flow, and groundwater recharge. The HYDRUS numerical models (HYDRUS (2D/3D), Šimůnek et al., 2006; HYDRUS-1D, Šimůnek et al., 2008) are used to illustrate these processes. More detail on the model simulations can be found in Radcliffe and Šimůnek (2010).

5.2 Steady Flow in Saturated Soil

5.2.1 Darcy Equation

The equation that describes steady water flow through soil was developed by H. Darcy (Darcy, 1856; Hubbert, 1956). For 1D flow, it can be written as

$$J_w = -K_s \frac{\partial H}{\partial z}, \tag{5.1}$$

where
    J_w is the volumetric flow rate of water per unit cross-sectional area (L T^{-1})
    K_s is the saturated hydraulic conductivity (L T^{-1})
    H is the total head (L)
    z is the spatial coordinate (L)

J_w may be positive or negative depending on flow direction (the usual convention is positive for flow up or to the right). Darcy's law can be extended to 2D and 3D flow.

Darcy's equation takes the same form as several other important laws in science, among them, Fick's law for molecular diffusion, Ohm's law for electric current flow, and Fourier's law for heat conduction. It shows that for water to move there must be a difference in water potential (see Chapter 4 for definition), but the rate of water flow will depend on the hydraulic gradient and the hydraulic conductivity of the soil.

5.2.2 Saturated Flow Parameters

For saturated flow, the most important soil parameter is saturated hydraulic conductivity, which is a function of the fluid and soil properties:

$$K_s = \frac{k\rho_l g}{\eta}, \tag{5.2}$$

where
    k is the *intrinsic permeability* of the soil (L^2)
    ρ_l is the density of the fluid (M L^{-3})
    g is the gravitational acceleration (L T^{-2})
    η is the coefficient of dynamic viscosity of the fluid (M L^{-1} T^{-1})

It is apparent from this equation that temperature has an effect on K_s since it will affect ρ_l and η. It is generally true that while a given soil will have a constant k as long as the soil structure is not affected by the liquid, it will have a different K_s for different fluids.

Soils with low porosity, few large pores, and poor interconnectivity between pores have low K_s. Rawls et al. (1982) compiled values of K_s from 1323 soils collected over 32 states of the United States. Average K_s for 11 of the 12 United States Department of Agriculture (USDA) soil textural classes (the silt class is missing) from Rawls et al. (1982) are shown in Table 5.1. Brooks and Corey (1964) water retention curve parameters (see Chapter 4 for information on water retention functions) are also shown. Saturated hydraulic conductivities were highest in coarse-textured soils (sand, loamy sand, etc.) and declined in fine-textured soils (clay, silty clay, etc.), due to larger pores in coarse-textured soils. This can be corroborated by examining air-entry pressure heads h_a (absolute value of the pressure head at which the largest capillary pore empties), which are higher in fine-textured soils, indicating that the largest capillary pore is relatively small.

Saturated hydraulic conductivity varies widely among soils within a textural class, especially in the more fine-textured classes in Table 5.1. In Figure 5.2, K_s for 324 soil samples from the UNsaturated SOil hydraulic properties Database (UNSODA)

TABLE 5.1 Brooks and Corey (1964) Soil Hydraulic Parameters (K_s, θ_r, θ_s, h_a, and λ) for 11 Textural Classes

Textural Class	K_s (cm day^{-1})	θ_r (cm^3 cm^{-3})	θ_s (cm^3 cm^{-3})	h_a (cm)	λ (−)	λ_c (cm)
Sand	504.0	0.020	0.417	−7.26	0.592	9.88

database (Nemes et al., 2001) are plotted as a function of clay content. Saturated hydraulic conductivity tends to decline as clay content increases, but there is considerable scatter at higher clay contents. The clayey soils with high K_s are probably soils with strong structure. Hence, soil structure as well as soil texture affects water flow in all but very sandy soils.

Saturated hydraulic conductivity is highly variable in space, not only in the vertical direction as horizons change but also in the horizontal direction within the same horizon (Nielsen et al., 1973; Russo and Bresler, 1980; Russo and Bouton, 1992). Saturated hydraulic conductivity also varies in time at much shorter scales than that of pedogenesis. This is especially true near the soil surface where land use, biology, and weather have more of an effect. Some authors have suggested that soil properties should be divided into static and dynamic properties (Grossman and Reinsch, 2002; Tugel et al., 2005). Hence, the effect of texture and mineralogy on K_s might be considered static, whereas other effects might be considered dynamic.

5.2.3 Flow Perpendicular to Layers

Most soils other than entisols and inceptisols have well-developed horizons or layers, which have different hydrologic characteristics including K_s. Above the water table, water usually flows vertically so that flow is perpendicular to these layers. Below the water table, flow can occur parallel to the layers.

Steady flow through a layered soil can be described by making an analogy with electric current flow through resistors in series (Jury and Horton, 2004). For a soil column with N layers of thickness L_1, …, L_N and saturated hydraulic conductivity K_1, …, K_N (column on the left side of Figure 5.3), the effective saturated hydraulic conductivity K_{eff} (L T^{-1}) is:

$$K_{eff} = \frac{\sum_{j=1}^{N} L_j}{\sum_{j=1}^{N} L_j/K_j}. \tag{5.3}$$

The effective hydraulic conductivity is not a simple arithmetic average of conductivities of individual layers or their limiting value, but a weighted average that considers the layer thicknesses as well as their conductivities. Thus, the thickness of layers is important.
FIGURE 5.3 A soil column with N layers of thickness L_1, …, L_N and saturated hydraulic conductivities K_1, …, K_N on the left. An equivalent uniform column on the right with a saturated hydraulic conductivity K_{eff}.

Because the flux across all layers is the same under steady-flow conditions, Darcy's law can be used to show that when water flows down through a high-conductivity to a low-conductivity layer (e.g., a sand horizon over a clay horizon), a pressure head occurs at the interface that is greater than would be present in a uniform soil. This elevated pressure slows flow through the upper layer and speeds flow through the lower layer until flow through both layers is the same. In the reverse situation, (e.g., a clay over a sand), the interface pressure head is less than in a uniform soil, which speeds flow through the upper layer and slows flow through the lower layer. In a saturated, layered soil under steady flow, the pressure head distribution is linear with depth within each layer but with a different rate of change.

For flow from low- to high-conductivity layers where a large difference in conductivity is present, negative pressure heads can occur at the interface that exceed the air-entry pressure head of soil in the lower layer. This causes unsaturated conditions in the lower layer that greatly reduce flow through the profile. This often occurs when a *surface seal* or *crust* is present. Another way to equalize flow through a layered soil with a low-conductivity layer over a high-conductivity layer is for water to flow through only part of the less restrictive layer. This is a form of *preferential flow* called *fingering*. Both surface seals and fingering are discussed later in this chapter.

5.2.4 Flow Parallel to Layers

For flow parallel to layers (which usually occurs below the water table), the resistances of particular layers can be considered in parallel (more water flows through high- than low-conductivity layers). If the soil layers are of equal thickness, then K_{eff} is the arithmetic average of the hydraulic conductivities. For layers of different thicknesses, K_{eff} is a weighted average where the layer thicknesses are the weights:

$$K_{\text{eff}} = \frac{\sum_{j=1}^{N} L_j K_j}{\sum_{j=1}^{N} L_j}. \tag{5.4}$$

5.2.5 Flow to a Drain

Flow to a drain provides another example of steady saturated flow (Dupuit, 1863; Forchheimer, 1930). An equation can be developed for the maximum height of the water table between two drains or ditches under steady-flow conditions (Warrick, 2003; Figure 5.4). For a steady rainfall or irrigation rate R (L T^{-1}) and a drain separation distance $2s$ (L) with the water level in the ditch or drain maintained at a height z_0 (L), the assumption is that water in the saturated zone will flow only in the horizontal direction and the gradient will be the change in height of the water table:

$$J_x = -K_s \frac{dz}{dx}, \tag{5.5}$$
FIGURE 5.4 Geometry considered for defining the Dupuit–Forchheimer drainage equation (5.6). Water height in the ditch or drain is z_0. (From Warrick, A.W. 2003. Soil water dynamics. Oxford University Press, Oxford, U.K.)

where z is the height of the water table (L). Under these conditions, it can be shown that the maximum height of the water table z_{max} (L) between the drains or ditches is

$$z_{\text{max}} = \sqrt{\frac{Rs^2}{K_s} + z_0^2}. \tag{5.6}$$

From this equation, it can be seen that the water table will not rise as high between the drains and ditches when K_s is large. Also, the greater the rainfall or irrigation rate, the higher the water table will rise. The larger the spacing between drains, the higher the water table will rise. Equation 5.6 can be used to determine the distance for separating drains in order to maintain the water table within a given range from the soil surface. This equation is also useful later in the chapter when we consider groundwater recharge and hillslopes.

5.3 Steady Flow in Unsaturated Soil

The unsaturated zone lies between the water table and the soil surface (Figure 5.1). In this region, the water content of the soil is less than saturation ($\theta < \theta_s$), many pores are air filled, and pressure heads are negative.

Rising above the water table is the capillary fringe, a zone where water is under tension but very near saturation. The capillary fringe is important for water flow because only a slight change in water content or pressure head can cause a sharp change in the water table position (Sklash et al., 1986). Also, lateral flow increases in this zone (Liu and Dane, 1996; Abit et al., 2008).

The thickness of the capillary fringe depends on the water retention curve and can be approximated by the air-entry pressure head (h_a). From Table 5.1, it is apparent that sands have thinner capillary fringes than unstructured clays. Capillary fringes are also found around other zones of saturation in the unsaturated zone, such as injection boreholes, surface seepage basins, and losing streams.

5.3.1 Buckingham–Darcy Equation

In the unsaturated zone, larger pores drain more readily than smaller pores, as can be noted using the capillary rise equation (see Chapter 4). Therefore, the hydraulic conductivity is much smaller under unsaturated than saturated conditions due to water moving through smaller pores or as films along the walls of larger pores. At very low water contents, continuous fluid paths may not exist and water may move in the vapor phase. The unsaturated hydraulic conductivity is therefore represented as a function of pressure head $K(h)$ or as a function of water content $K(\theta)$. Buckingham (1907) modified Darcy's equation for unsaturated flow as follows:

$$J_w = -K(h)\frac{\partial H}{\partial z} = -K(h)\frac{\partial (h+z)}{\partial z} = -K(h)\left(\frac{\partial h}{\partial z} + \frac{\partial z}{\partial z}\right)$$

$$= -K(h)\left(\frac{\partial h}{\partial z} + 1\right), \qquad (5.7)$$

where the total head or hydraulic head is the sum of the pressure head and gravitational head, $H = h + z$.

5.3.2 Unsaturated Hydraulic Conductivity

As is the case with the water retention functions, equations have been developed to describe the hydraulic conductivity function. One of the simplest equations is the Gardner (1958) equation:

$$K(h) = K_s\,e^{\alpha h}, \qquad (5.8)$$

where α (L^{-1}) is a positive constant dependent on the soil. Since h is negative, the exponential term causes $K(h)$ to drop rapidly as h becomes more negative. A coarse-textured soil (sand), which has a rapidly decreasing hydraulic conductivity function compared to a fine-textured soil (clay), would be expected to have a larger value of α.

Other simple equations include the Campbell (1974) equation:

$$K(\theta) = K_s\left(\frac{\theta}{\theta_s}\right)^m, \qquad (5.9)$$

where m is a fitting parameter [-], and the Haverkamp equation (Haverkamp et al., 1977)

$$K(h) = \frac{K_s}{1 + (h/a)^N}, \qquad (5.10)$$

where a (L^{-1}) and N [-] are fitting parameters.

Many hydraulic conductivity functions have been derived using the pore-size distribution models of Burdine (1953) or Mualem (1976), in combination with various water retention functions (water retention functions are discussed in Chapter 4). The Brooks and Corey (1964) retention equation is commonly associated with Burdine's pore-size distribution model, leading to the hydraulic conductivity function:

$$K(S_e) = K_s S_e^{1+l+2/\lambda}, \qquad (5.11)$$

where

λ [-] is the pore-size distribution index from the Brooks and Corey (1964) water retention function (see Table 5.1)

l is a pore-connectivity parameter (assumed to be 2.0)

S_e is effective saturation [-]:

$$S_e = \frac{\theta - \theta_r}{\theta_s - \theta_r}, \qquad (5.12)$$

where

θ_s is the saturated volumetric water content (L^3 L^{-3})

θ_r is the residual volumetric water content (L^3 L^{-3})

The van Genuchten (1980) water retention function is similarly coupled most often with the model of Mualem to give

$$K(S_e) = K_s S_e^l[1 - (1 - S_e^{1/m})^m]^2 \qquad (5.13)$$

where m [-] and n [-] are empirical shape parameters from the van Genuchten (1980) water retention function and it is assumed that

$$m = 1 - \frac{1}{n}, \quad n > 1. \qquad (5.14)$$

The pore-connectivity parameter l in Equation 5.13 was estimated by Mualem (1976) to be 0.5 as an approximate average for many soils. However, Schaap and Leij (2000) recommended using $l = -1$ as an appropriate value for most soil textures.

Finally, Durner (1994) associated a *dual-porosity* retention model with Mualem's pore-size distribution model to give

$$K(S_e)$$

$$= K_s\frac{(w_1 S_{e_1} + w_2 S_{e_2})^l\{w_1\alpha_1[1 - (1 - S_{e_1}^{1/m_1})^{m_1}] + w_2\alpha_2[1 - (1 - S_{e_2}^{1/m_2})^{m_2}]\}^2}{(w_1\alpha_1 + w_2\alpha_2)^2},$$

$$(5.15)$$

where

w_i [-] are the weighting factors for the overlapping regions of the water retention functions

α_i [-] and m_i [-] are fitting parameters for the separate functions S_{ei} ($i = 1, 2$)

Values of $K(h)$ vary by orders of magnitude with pressure head, are sensitive to texture, clay mineralogy, and structure, and are highly variable in space and (in some cases) time.

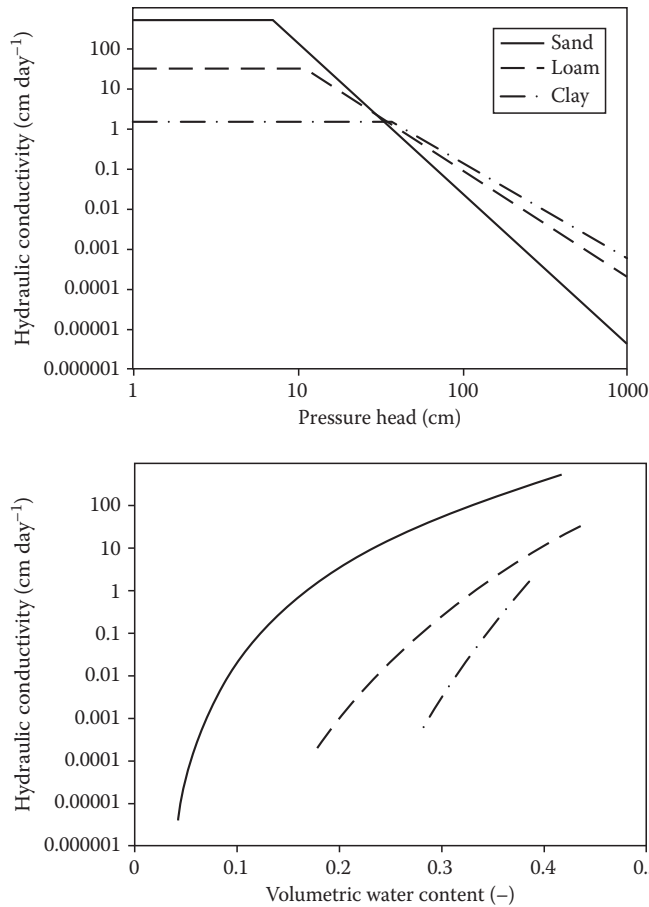
Figure 5.5 presents examples of hydraulic conductivity functions for the sand, loam, and clay textural classes, using the


FIGURE 5.5 Examples of unsaturated hydraulic conductivity curves as a function of pressure head (top) and volumetric water content (bottom) for the sand, loam, and clay soil textural classes based on the Brooks and Corey (1964) equation (Equation 5.11) and parameters in Table 5.1.

Brooks and Corey (1964) unsaturated hydraulic conductivity equation (Equation 5.11) and the parameters given in Table 5.1. The hydraulic conductivity curves are presented as functions of both the pressure head (top) and water content (bottom). It is apparent that Equation 5.11 results in a linear relationship between ln $K(h)$ and ln h. Notice that the hydraulic conductivity at saturation is significantly larger for the sand than for the loam or clay. This difference is often several orders of magnitude. Also notice that the hydraulic conductivity decreases several orders of magnitude as the soil becomes unsaturated. This decrease, when expressed as a function of the pressure head (Figure 5.5, top), is much more significant for the sand than for the loam, and even more so than for the clay. The decrease for the sand is so dramatic that eventually the hydraulic conductivity becomes smaller than for the loam or clay. These properties of the hydraulic conductivity function are sometimes used in the design of capillary barriers in landfill covers to divert water from flowing through the underlying waste or in thin sand or gravel layers at the soil surface to prevent or limit evaporation.

5.3.3 Macroscopic Capillary Length

A useful way to quantify the unsaturated hydraulic conductivity function in a single parameter is in terms of the *macroscopic capillary length* λ_c (L) defined as

$$\lambda_c = \frac{\int_{h_i}^{h_0} K(h)\,dh}{K(h_0) - K(h_i)}, \tag{5.16}$$

where

h_0 (L) is a pressure head at or near zero
h_i (L) is a more negative pressure head such that $h_0 > h_i$ (White and Sully, 1987)

There are a number of ways to interpret λ_c. One way is a $K(h)$-weighted average pressure head over the range from h_0 to h_i (except that it is a positive number). If λ_c is small, this indicates that the *effective pressure head* for unsaturated flow is near zero. In other words, $K(h)$ is negligible except for pressure heads near zero (and water contents near saturation). This would be the case for a sand where $K(h)$ rises sharply at the wet end of the curve. An unstructured clay might have a larger λ_c, because the effective pressure head for unsaturated flow is more negative and $K(h)$ does not approach zero as fast at the dry end of the curve. Typical values for λ_c in four broad groups of soils are shown in Table 5.2. The effect of structure in fine-textured soils is apparent in that an unstructured clay has a λ_c of 25 cm, whereas a structured clay has a λ_c of 2.8 cm. Values for λ_c are also shown in Table 5.1 for each of the textural classes. These values were calculated using Equation 5.16 with $h_0 = 0$ cm, $h_i = -15{,}000$ cm, and the Brooks and Corey (1964) equation for $K(S_e)$ (Equation 5.11). In both tables, leaving aside the effect of structure, λ_c increases as the clay content increases.

If the Gardner equation (Equation 5.8) is used to describe $K(h)$ in Equation 5.16, it can be shown that

$$\lambda_c = \frac{1}{\alpha}. \tag{5.17}$$

TABLE 5.2 Soil Texture/Structure Categories for Estimation of Macroscopic Capillary Length (λ_c)

Soil Texture/Structure Category	λ_c (cm)
Coarse and gravelly sands; may also include some highly structured soils with large cracks and/or macropores	2.8
Most structured soils from clays through loams; also includes unstructured medium and fine sands	8.3
Soils that are both fine textured (clayey) and unstructured	25
Compacted, structureless, clayey materials such as landfill caps and liners, lacustrine or marine sediments, etc.	100

Source: Adapted from Elrick, D.E., and W.D. Reynolds. 1992. Infiltration from constant-head well permeameters and infiltrometers, p. 1–24. *In* G.C. Topp, W.D. Reynolds, and R.E. Green (eds.) Advances in measurement of soil physical properties: Bringing theory into practice. SSSA, Madison, WI.

Thus, a small value of λ_c indicates a rapid exponential decrease of the $K(h)$ function. Macroscopic capillary length appears in a number of equations later in this chapter, where it represents the effect of soil texture (and the shape of the unsaturated hydraulic conductivity curve) on unsaturated water flow.

5.3.4 Analytical Solutions for Steady Flow

It is useful to consider several cases of steady unsaturated flow. Although true steady flow may occur only rarely under unsaturated conditions, transient flow (discussed later in this chapter) usually approaches steady flow over long time periods, and the steady flow equations help to show what factors may be important under transient conditions.

As noted before, steady 1D flow in a uniform soil can be described by the Buckingham–Darcy equation (Equation 5.7). If the water content is uniform with depth, then $\partial h/\partial z = 0$, only gravity causes flow and the flux is equal to the hydraulic conductivity:

$$J_w = -K(h). \tag{5.18}$$

In this case, h is the same at all depths. This is called *gravity flow* or *unit-gradient flow*.

Analytical solutions to the Buckingham–Darcy differential equation (Equation 5.7) have been developed for a number of steady-flow conditions. The usual procedure is to rewrite the equation in an integral form (Jury and Horton, 2004):

$$\int_{h_1}^{h_2} \frac{dh}{1 + (J_w/K(h))} = z_1 - z_2. \tag{5.19}$$

If the equation for $K(h)$ is such that the integral on the left side can be evaluated (has an *analytical solution*), then the differential equation can be solved.

An example is steady infiltration ($J_w = -i$) in a uniform soil from the surface to a water table at depth L (Jury and Horton, 2004). This might occur in a soil remediation effort designed to flush contaminants from the unsaturated zone down into the capture zone of a well. In this case, $h_1 = 0$ at the water table, where $z_1 = -L$. The other limit is an arbitrary depth below the surface ($h_2 = h$ and $z_2 = z$) so that integration will result in an equation for the distribution of h with depth under steady flow conditions. The $K(h)$ function is described using the Haverkamp equation (Equation 5.10). To get an integral that can be evaluated, it is assumed that $N = 2$ in the Haverkamp equation. It can be shown (Jury and Horton, 2004) that the solution is

$$h = a\sqrt{\frac{K_s}{i} - 1}\,\tanh\left[-\frac{\sqrt{(1 - (i/K_s))(i/K_s)}}{a}(L + z)\right], \tag{5.20}$$

where $\tanh(x)$ is the hyperbolic tangent function.
FIGURE 5.6 Distribution of h as a function of z for a steady low infiltration rate ($0.5\,\text{cm day}^{-1}$) and a steady high infiltration rate ($1.5\,\text{cm day}^{-1}$) based on Equation 5.20.

The distribution of h versus z predicted by Equation 5.20 for a Chino clay with $K_s = 1.95\,\text{cm day}^{-1}$, $a = -23.8\,\text{cm}$, and $N = 2$ (Gardner and Fireman, 1958) is shown for a low ($i = 0.5\,\text{cm day}^{-1}$) and a high ($i = 1.5\,\text{cm day}^{-1}$) infiltration rate in Figure 5.6. The distribution of h is curvilinear, contrary to a uniform or a layered saturated soil, especially with the lower infiltration rate, which causes a lower h at the surface. At the water table, the pressure head is zero, of course. Near the surface, especially at the high infiltration rate, the curve is nearly vertical indicating that gravity flow is the dominant form of flow (Equation 5.18).

Another example of steady downward flow is 3D water flow from a point source such as a ring placed at the soil surface (Figure 5.7). A steady infiltration rate will be approached after a period of time. Wooding (1968) developed an equation for these circumstances:

$$i_s = K(h_0)\left(1 + \frac{4\lambda_c}{\pi r}\right), \tag{5.21}$$
FIGURE 5.7 Steady 3D infiltration of water from a ring of radius r at the soil surface.

where

i_s is the steady infiltration rate (L T^{-1})

r is the radius of the ring (L)

$K(h_0)$ is the hydraulic conductivity (L T^{-1}) corresponding to the pressure head of the water supply at the soil surface ($z = 0$)

It is apparent by comparing Equations 5.21 and 5.18 that the second term in Equation 5.21 accounts for the increased infiltration rate from a ring due to lateral flow into dry soil (Figure 5.7). It is no surprise that this term includes λ_c since this represents the effect of capillarity, which will vary with soil texture and the shape of the $K(h)$ function. If water is ponded at the surface, $h_0 > 0$ and $K(h_0)$ should be what corresponds to K_s in the field. Experiments have shown that the *field-saturated hydraulic conductivity* (K_{fs}) is less than the saturated hydraulic conductivity that would be measured on a carefully saturated, intact core in the lab (K_s). This has been attributed to the effect of entrapped air under field conditions that reduces the cross-sectional area available for water flow and the water potential gradient. Bouwer (1969) recommended using a value for K_{fs} equal to one-half of K_s for predicting the steady-state infiltration rate.

The Buckingham–Darcy differential equation can also be solved for steady flow from a borehole (Figure 5.8):

$$Q_s = K_s \left(\pi r^2 + \frac{H\lambda_c}{G} + \frac{H^2}{G} \right), \qquad (5.22)$$

where

Q_s is the steady volumetric flow rate (L^3 T^{-1})

H is the height of water ponded in the borehole (L)

r is the radius of the hole (L)

G is a dimensionless geometric factor that depends primarily on the ratio of H/r (Elrick and Reynolds, 1992)

If the steady infiltration flux i_s is defined as the volumetric flow rate divided by the cross-sectional area of the borehole $Q_s/\pi r^2$,
FIGURE 5.8 Steady 3D infiltration of water from a borehole.

TABLE 5.3 Dimensionless Coefficients for the Polynomial (Equation 5.24) Describing the Geometric Factor *G*, Valid for *H/r* < 10

Soil Texture/Structure	A_1	A_2	A_3	A_4
Sand	0.079	0.516	−0.048	0.002
Structured loams and clays	0.083	0.514	−0.053	0.002
Unstructured clays	0.094	0.489	−0.053	0.002

Source: Bosch, D.D., and L.T. West. 1998. Hydraulic conductivity variability for two sandy soils. Soil Sci. Soc. Am. J. 62:90–98.

the equation can be expressed in a form comparable to the Wooding equation (Equation 5.21):

$$i_s = K_s \left(1 + \frac{H\lambda_c}{G\pi r^2} + \frac{H^2}{G\pi r^2} \right). \qquad (5.23)$$

The similarity between Equation 5.23 and the Wooding equation (Equation 5.21) is apparent. In sequence, the terms inside the brackets in Equation 5.23 account for the effect of gravity, the shape of the unsaturated hydraulic conductivity function (note the λ_c term), and hydrostatic pressure in the borehole.

Bosch and West (1998) fitted a polynomial equation to the data of Elrick and Reynolds (1992) to determine the value of *G*:

$$G = \frac{1}{2\pi} \left[A_1 + A_2 \frac{H}{r} + A_3 \left(\frac{H}{r} \right)^2 + A_4 \left(\frac{H}{r} \right)^3 \right]. \qquad (5.24)$$

The values of the coefficients $A_1, \ldots, A_4$ [-] in this polynomial depend on texture and structure (Table 5.3). Equation 5.22 is used to measure K_s using a borehole permeameter, described later in this chapter.

5.4 Transient Water Flow

In this and the following sections, we address transient water movement. Analytical solutions of the differential equations that govern soil water flow for nonsteady, unsaturated flow conditions are very few. Simplifications of the unsaturated flow equations have been developed to describe infiltration because of the importance of this transient flow process. Alternatively, numerical models are commonly used to solve most transient flow problems in the unsaturated zone.

5.4.1 Governing Equations

Here, we discuss the Richards equation and the initial conditions and boundary conditions that apply to transient water flow.

5.4.1.1 The Richards Equation

A conservation equation for nonsteady vertical water flow can be developed by considering a representative elementary volume. The water flux into this volume during a small time interval

Δt must be equal to the water flux out of the volume, plus the change in water stored within the volume, and any sources or sinks. The resulting conservation equation is

$$\frac{\partial \theta}{\partial t} = -\frac{\partial J_w}{\partial z} - S(h), \tag{5.25}$$

where

 θ is the volumetric water content ($L^3 L^{-3}$)
 t is time (T)
 z is the spatial coordinate (L) (positive upward)
 J_w is the water flux ($L T^{-1}$)
 $S(h)$ is a pressure head dependent sink ($L^3 L^{-3} T^{-1}$) (a negative S is a source), usually accounting for root water uptake (transpiration)

Equation 5.25 is often referred to as the *mass conservation equation* or the *continuity equation*. The conservation equation must be combined with one or several equations describing J_w to produce the governing equation for variably saturated water flow. Formulations of governing equations for the different types of flow (uniform and preferential flow) are all based on this continuity equation. If the Buckingham–Darcy equation (Equation 5.7) is substituted for J_w, the result is

$$\frac{\partial \theta(h)}{\partial t} = \frac{\partial}{\partial z}\left(K(h)\frac{\partial h}{\partial z}\right) + \frac{\partial K(h)}{\partial z} - S(h). \tag{5.26}$$

This partial differential equation, first developed by Richards (1931), is the equation governing flow in the unsaturated zone. The first term on the right-hand side accounts for the effect of capillarity on water movement and the second term on the right-hand side accounts for the effect of gravity. It can be expanded to two and three dimensions.

Equation 5.26 is the *mixed form* of the Richards equation in that there are two dependent variables: θ and h. Various other formulations of the Richards equation are possible. For example, when the time derivative of the water content is expanded using the chain rule as follows:

$$\frac{\partial \theta h}{\partial t} = \frac{d\theta}{dh}\frac{\partial h}{\partial t} = C_w(h)\frac{\partial h}{\partial t} \tag{5.27}$$

one obtains the *pressure-head form*

$$C_w(h)\frac{\partial h}{\partial t} = \frac{\partial}{\partial z}\left(K(h)\frac{\partial h}{\partial z}\right) + \frac{\partial K(h)}{\partial z} - S(h), \tag{5.28}$$

where $C_w(h)$ is the soil water (or hydraulic) capacity function (L^{-1}) that characterizes the slope of the retention curve. The only independent variable is h:

The Richards equation (in any form) is a nonlinear partial differential equation. It is similar to the heat-flow equation that includes convection and conduction but differs in one very important way. The coefficient $K(h)$ that multiplies the gradient term is a function of the dependent variable h. This makes it a *nonlinear* partial differential equation. Because of its strongly nonlinear makeup, only a relatively few simplified analytical solutions can be derived. Most practical applications of the Richards equation require a numerical solution (see Section 5.6). Alternatively, the equation is simplified in some manner as happens with infiltration equations (see Section 5.7.3).

5.4.1.2 Initial Conditions

The solution to the Richards equation will depend on the initial and boundary conditions specified. Initial conditions characterizing the initial state of the system can be specified either in terms of the water content

$$\theta(z,t) = \theta_i(z,0) \tag{5.29}$$

or the pressure head

$$h(z,t) = h_i(z,0), \tag{5.30}$$

where θ_i ($L^3 L^{-3}$) and h_i (L) are initial values of water content and pressure head, respectively. For numerical models, it is generally best to specify initial conditions in terms of the pressure head, since this variable is the driving force for water flow. Specifying initial conditions in terms of the water content often leads to unrealistically large pressure-head gradients, and consequently water fluxes, across textural boundaries.

5.4.1.3 Boundary Conditions

Two types of conditions can be specified on boundaries of the transport domain: system-dependent and system-independent boundary conditions. System-independent boundary conditions are boundary conditions for which the specified boundary value (i.e., pressure head, water content, water flux, or gradient) does not depend on the status of the soil system. System-dependent boundary conditions are boundary conditions for which the actual boundary condition depends on the status of the system and is calculated by the model itself.

Several system-independent boundary conditions may be applied to the transport domain boundaries. When the pressure head at the boundary is known, one can use the *Dirichlet* or *type-1* boundary condition:

$$h(z, t) = h_0(z,t), \tag{5.31}$$

where h_0 is a prescribed pressure head (L). This boundary condition is often referred to as a *pressure-head boundary condition*. This boundary condition must be used when simulating ponded infiltration; for describing the hydrostatic pressure at

the boundary between the soil and standing or flowing water in a furrow, lake, or river; to specify the water level in a well; or to define the position of the groundwater table. The water flux across a Dirichlet boundary is not known a priori but must be calculated from the mathematical solution (either analytical or numerical) of the governing flow problem.

When the water flux across the boundary is known, one can use the *Neumann* or *type-2* boundary condition:

$$-K(h)\left(\frac{\partial h}{\partial z}+1\right)=J_0(z,t),\qquad(5.32)$$

where J_0 is a prescribed water flux (L T^{-1}). This boundary condition is often referred to as a *flux boundary condition*. A Neumann boundary condition must be used only along boundaries where the flux is known, provided the flux does not depend on the soil system. Hence, this boundary condition cannot be used to model precipitation or irrigation since the precipitation or irrigation rate may exceed the infiltration capacity of the soil, in which case ponding will occur and the actual boundary flux will decrease.

A particular form of the type-2 boundary condition is the *gradient boundary condition*:

$$\frac{\partial h}{\partial z}+1=g_0(z,t),\qquad(5.33)$$

where g_0 is a prescribed total gradient (L L^{-1}). Equation 5.33 is commonly used to specify a unit vertical hydraulic gradient simulating free drainage from the bottom of a soil profile when the water table is situated far below the domain of interest. The condition is consistent with unit-gradient conditions (see Equation 5.18) often observed in field studies of water flow, especially during redistribution (Sisson, 1987; McCord, 1991).

In many applications, neither the flux across nor the pressure head or gradient at a boundary is known a priori but follows from interactions between the soil and its surroundings (e.g., the atmosphere or deeper subsurface). The boundary representing the soil–air interface, which is exposed to atmospheric conditions, is one example of the system-dependent boundary. The potential water flux across this interface is controlled exclusively by external conditions (precipitation or evaporation). However, the actual flux depends also on the (transient) moisture conditions in the soil. Soil surface boundary conditions may change from prescribed flux to prescribed head conditions (and vice versa). This occurs, for example, when the precipitation rate exceeds the infiltration capacity of the soil, resulting in either surface runoff or accumulation of excess water on top of the soil, depending upon the soil conditions. The infiltration rate in that case is not controlled anymore by the precipitation rate but instead by the infiltration capacity of the soil. A system-dependent boundary condition also occurs when the potential evaporation rate, as calculated from meteorological conditions (the evaporative demand of the atmosphere), exceeds the capability of the soil to deliver enough water toward the soil surface. In this case, the potential

evaporation rate can be significantly reduced to an actual evaporation rate that is again controlled by the soil.

System-dependent atmospheric boundary conditions can be implemented mathematically using an approach of Neuman et al. (1974), which limits the absolute value of the flux such that the following two conditions are satisfied:

$$\left|K(h)\left(\frac{\partial h}{\partial z}+1\right)\right|\le E\qquad(5.34)$$

and

$$h_A\ ''\ h\ ''\ h_S,\qquad(5.35)$$

where

E is the maximum potential rate of infiltration or evaporation under the current atmospheric conditions (L T^{-1})

h is the pressure head at the soil surface (L)

h_A and h_S are, respectively, the minimum and maximum pressure heads allowed under the prevailing soil conditions (L)

The value for h_A is determined from the equilibrium conditions between soil, water, and atmospheric water vapor, whereas h_S is usually set equal to zero (which would initiate instantaneous surface runoff) or results from the accumulation of excess water in the surface ponding layer, in which case its value must be calculated from the difference between the infiltration and precipitation (or irrigation) rates. When one of the limits of Equation 5.35 is reached, a prescribed head boundary condition will be used to calculate the actual surface flux. Methods for calculating E and h_A on the basis of atmospheric data have been discussed by Feddes et al. (1974).

Another example of a system-dependent boundary condition is a seepage face through which water leaves the saturated part of the flow domain. The boundary condition in this case can be formulated mathematically as follows:

$$\begin{aligned}J_0(z,t)&=0\quad\text{for }h(z,t)<0,\\ h_0(z,t)&=0\quad\text{for }h(z,t)\ge0.\end{aligned}\qquad(5.36)$$

This boundary condition states that there is no flux across the boundary as long as the boundary is unsaturated and that the pressure head changes to zero once saturation is reached. The flux across the boundary is then calculated from the flow field by solving the governing flow equations. This boundary condition can be used at the bottom of certain types of lysimeters or along tile drains.

A special system-dependent boundary condition is sometimes implemented in 1D numerical models (e.g., van Dam et al., 1997; Šimůnek et al., 2006) to account for flow to horizontal subsurface tile drains. An equivalent drainage flux from the bottom of the simulated soil profile is then calculated using an appropriate analytical solution for the tile drainage system (e.g., Hooghoudt, 1940; Ernst, 1962; van Hoorn, 1997). The drainage equations involved generally hold for steady-state flow into the drain and depend

upon the geometry of the system (e.g., depth of tile drain, depth to impermeable layer, location of water table midway between two drains, and possibly information about soil layering).

5.5 Measurements of Hydraulic Properties

Accurate measurement of hydraulic parameters by both laboratory and field methods is essential for the prediction of water movement in soils. However, uncertainties in parameter estimates arise because of spatial variation, measurement accuracy, and scale effects. Many of these methods use steady flow conditions but recent advances have been made in using transient conditions. The important laboratory and field methods commonly employed in estimating hydraulic properties using steady-flow conditions are discussed below with additional procedures available in Dane and Topp (2002). Transient flow methods using inverse solutions and parameter optimization are also discussed. Lastly, pedotransfer functions (PTFs) as an alternative to direct measurement of hydraulic properties are described.

5.5.1 Laboratory Methods

The constant-head and falling-head methods are common for measuring K_s. In the former method, a constant head of water is maintained at the top and bottom of a soil core and the steady water flux J_w is recorded (Reynolds and Elrick, 2002a). The gradient is known, given the heads at the top and bottom of the core and the length of the core, so Darcy's equation (Equation 5.1) can be used to determine K_s.

In the falling-head method, a standpipe is attached to the top of a soil core and the head at the top is allowed to drop over time (Reynolds and Elrick, 2002c). Under these conditions, it can be shown that

$$K_s = \frac{L}{t_1} \ln\left(\frac{b_0 + L}{b_1 + L}\right), \qquad (5.37)$$

where

b_0 is the height of water ponded (L) at the top of the core at time zero

b_1 is the height of water ponded (L) at a later time t_1 (T)

The falling-head method is useful in soils with very low K_s, where it is difficult to collect sufficient drainage from a core to measure J_w accurately within an interval of several hours. The initial reading b_0 can be recorded and the core left overnight before recording b_1 without concern about the effect of evaporation on the collected drainage.

Values of K_s measured on cores in the laboratory will depend on what measures are used to remove entrapped air from the soil before making the measurement. Flushing the core with CO_2, wetting the core slowly from the bottom, and measuring K_s under conditions of an upward flux are commonly used.

A number of methods have been developed for measuring unsaturated hydraulic conductivity on cores in the laboratory. Unsaturated hydraulic conductivity can be measured in a manner similar to the constant-head method for K_s by adding water at the top of the core at a rate that does not cause ponding (Booltink and Bouma, 2002a). The total potential within the core is measured at two heights using miniature tensiometers and the steady flux is recorded. The Buckingham–Darcy equation (Equation 5.7) is solved for $K(h)$, where h in this case is the average pressure head within the core. Steady evaporation from the top of a core can also be used to measure $K(h)$ by placing tensiometers at several heights, recording the steady evaporation rate, and calculating the gradient between each pair of tensiometers (Arya, 2002).

Steady unsaturated flow can be imposed on a long soil core by supplying water continuously at a rate less than K_s. This can be done by applying a crust made of a mixture of gypsum and sand, or cement and sand, to the soil surface (Booltink and Bouma, 2002b). The steady water flux is measured with a constant positive head above the crust. Because of the low K_s of the crust, flow in the core is unsaturated (see Section 5.2.3). A tensiometer in the core records h, and if a unit gradient is assumed, then the measured flux is $K(h)$. Successive flux measurements with different crusts, each with a different conductivity, provide measurements of $K(h)$ over the range of pressures achieved. Bouma and Denning (1972) used this method in the field, as well.

In all laboratory methods of measuring K_s and $K(h)$, the effect of the chemistry of the added water on clay dispersion must be considered. The goal is to prevent dispersion so that pore-size distribution and connectivity do not change during the measurement, which can be achieved by using a dilute solution with a divalent cation (Chiang et al., 1987).

5.5.2 Field Methods

Common field methods for measuring K_s are use of the ring infiltrometer and borehole permeameter. Ring infiltrometers can be used to pond water on the soil surface and measure the soil infiltration rate (Reynolds et al. 2002). It is usually assumed that the Wooding equation (Equation 5.21) describes the 3D steady infiltration rate. Typical values of λ_c (Table 5.1 or 5.2) can be used to convert steady flow rates to K_s using this equation. Concentric double rings have been used to force 1D flow in the interior ring. In this case, the steady infiltration rate is an estimate of K_s in a uniform soil. However, Bouwer (1986) found that, for the typical dimensions used in a double ring, flow was not 1D.

Borehole permeameters are used to measure saturated hydraulic conductivity below the soil surface in the unsaturated zone (Reynolds and Elrick, 2002b). They consist of a Mariotte siphon (McCarthy, 1934) that maintains water at a constant level in a borehole and they allow measurement of the flow rate into the soil. The steady flow rate into the borehole Q_s is measured and then Equation 5.22 applies, but there are two unknowns in this equation: K_s and λ_c. One approach is to measure Q_s at two values of H in the same borehole and solve simultaneous equations for K_s and λ_c. Since changing the level of H in the borehole necessarily changes the region of soil that is being sampled, soil heterogeneity in the form of layering or macropores can result in unrealistic and invalid (i.e., negative) K_s and λ_c. As many as

30%–80% of measurements of K_s and λ_c in structured soils may be invalid (both negative) according to Elrick and Reynolds (1992). Alternatively, a single measurement of Q_s may be used and λ_c estimated using Table 5.1 or 5.2. Studies suggest that this method yields values of K_s that are usually accurate to within a factor of 2 (Reynolds et al., 1992).

Tension infiltrometers (also called disc permeameters) are a popular method for determining unsaturated hydraulic conductivity and other hydraulic parameters in field soils. They consist of a circular porous plate or membrane, which is placed on the soil surface or an excavated surface. Water is supplied to the plate under tension using a Mariotte bottle arrangement and the rate of water entry into the soil can be measured on a graduated cylinder or with a pressure transducer (Clothier and Scotter, 2002). In some cases, a ring is attached to the tension infiltrometer to allow ponded infiltration measurements at the same location (Perroux and White, 1988). Two approaches are common, one in which the infiltration rate is measured after it attains a steady rate and the other in which the early nonsteady infiltration rate is measured (Warrick, 1992).

5.5.3 Inverse Solutions and Parameter Optimization

Modeling transient water flow requires an accurate estimation of a number of hydraulic parameters including the soil water retention curve, saturated hydraulic conductivity, and the unsaturated hydraulic conductivity function. As an alternative to direct measurement of these parameters, they can be estimated indirectly using *inverse modeling*. This differs from the direct methods where steady-flow conditions are required due to the analytical solutions that are used. Whereas steady-state methods invert Darcy's equation, transient methods invert the Richards equation. Inverse methods for these conditions have become possible because advances in computer science have made obtaining numerical solutions much quicker, so solutions can be run repeatedly to find the optimum parameter values.

Inverse modeling is a form of model calibration, which is frequently used in hydrology (Gupta et al., 2003). It requires a set of observed data such as measured water contents or pressure heads. In model calibration, the objective is usually to obtain better model predictions. Parameter optimization differs in that the objective is to determine the best estimate of the parameters as an alternative to directly measuring them.

The HYDRUS models have an inverse modeling capability. The objective function Φ that is minimized in HYDRUS-1D is defined as

$$\Phi(b,q,p) = \sum_{j=1}^{m_q} v_j \sum_{i=1}^{n_{qj}} w_{i,q}[q_j^\star(z,t_i) - q_j(z,t_i,b)]^2$$

$$+ \sum_{j=1}^{m_p} \bar{v}_j \sum_{i=1}^{n_{pj}} \bar{w}_{i,q}[p_j^\star(\theta_i) - p_j(\theta_i,b)]^2 + \sum_{j=1}^{n_b} \hat{v}_j(b_j^\star - b_j)^2.$$

$$(5.38)$$

The first term on the right-hand side of Equation 5.38 represents the deviations between measured and predicted variables

such as pressure heads or water contents at different depths and times. Predicted and measured fluxes or cumulative fluxes across boundaries can also be used as variables. In the first term, m_q is the number of different sets of measurements, n_{qj} is the number of measurements in a particular measurement set, $q_j^\star(z,t_i)$ represents specific measurements at time t_i for the jth measurement set at depths z (a vector of locations), $q_j^\star(z,t_i,b)$ are the corresponding model predictions for the vector of optimized parameters (e.g., θ_r, θ_s, α, n, K_s, etc.) and v_j and w_{ij} are weights associated with a particular measurement set or point, respectively. The second term on the right-hand side of Equation 5.38 represents differences between independently measured and predicted soil hydraulic properties (e.g., $\theta(h)$ or $K(h)$ data), while the terms m_p, n_{pj}, $p_j^\star(\theta_i)$, $p_j(\theta_i,b)$, $\bar{v}_j$, and $\bar{w}_{ij}$ have similar meanings as for the first term but now apply to hydraulic properties. The last term on the right-hand side of Equation 5.38 represents a penalty function for deviations between prior knowledge of the soil hydraulic parameters $b_j^\star$ and their final estimates b_j, with n_b being the number of parameters with prior knowledge and $\hat{v}_j$ representing preassigned weights. Minimization of the objective function is accomplished in HYDRUS using the Levenberg–Marquardt nonlinear minimization (Marquardt, 1963).

Transient flow parameter optimization methods are described by Hopmans et al. (2002). With these methods, both the soil retention and unsaturated hydraulic conductivity functions can be estimated from a single transient experiment. Inverse methods can be used in laboratory experiments and in field experiments. A common laboratory experiment is the multistep outflow method. In this method, a pressure cell similar to what is used for the determination of a water retention curve is employed. The air pressure on the cell is increased once (the *one-step method*) or a number of times to successively higher pressures (the *multistep method*) much like what is done when measuring a water retention curve. However, instead of waiting until the cell reaches equilibrium at a given pressure to measure the water content, pressure head in the cell and water flow out of the cell are measured continuously during the experiment. The observed and predicted pressure heads in a multistep method experiment analyzed using HYDRUS-1D are shown in Figure 5.9. Four pressure changes were used and the experiment ran for nearly 200 h. After eight iterations, HYDRUS-1D reduced the objective function sufficiently for the final parameters to be considered optimized. Other transient flow experiments that can be used for parameter optimization include evaporation, use of a tension infiltrometer, and field drainage (Hopmans et al., 2002).

5.5.4 Pedotransfer Functions

Considering that direct measurements of the unsaturated soil hydraulic properties are relatively difficult and time consuming, many have attempted to predict soil hydraulic properties from more easily measurable surrogate properties, such as soil texture. Relationships between the soil hydraulic and other properties are commonly called PTFs. The functions are usually obtained using
FIGURE 5.9 Observed pressure head (circles) and predicted pressure head (curve) in a multistep outflow experiment analyzed using HYDRUS-1D.

various mathematical and statistical approaches, such as regression (Rawls and Brakensiek, 1985; Vereecken et al., 1989, 1990; Rawls et al., 1991) or neural network analysis (Schaap et al., 1998; Schaap and Leij, 2000). PTFs can be used to predict either the soil hydraulic properties directly, such as the water content at specified pressure heads or the saturated hydraulic conductivity, or parameters in the analytical models used for the soil hydraulic properties (Rawls and Brakensiek, 1985; Vereecken et al., 1989, 1990). Recent reviews of PTFs are given by Leij et al. (2002) and Pachepsky et al. (2006).

The HYDRUS models implement the Rosetta Lite module of Schaap et al. (2001) to predict soil hydraulic parameters using five different levels of input data. The simplest model (Model 1) uses the average of fitted hydraulic parameters within a textural class in the USDA textural triangle. The four other models use progressively more detailed input data, starting with the sand, silt, and clay

fractions (Model 2), then adding a measured bulk density (Model 3), and water contents at 33 (Model 4) and 1500 kPa (Model 5).

Although very convenient to use, PTFs can produce relatively large errors in the predicted soil hydraulic properties. Schaap et al. (1998) and Schaap and Leij (1998) reported that the root mean square errors (RMSE) for water content and $\log(K_s)$ predictions were 0.108 and 0.741, respectively, using the simplest Rosetta model (Model 1). They still obtained relatively large RMSE values of 0.063 and 0.610 for water contents and $\log(K_s)$, respectively, with Model 5 that requires the most detailed information. Other studies found that the accuracy for predicting water content using various PTFs is relatively good (RMSE of $0.02–0.11\,cm^3\ cm^{-3}$) compared to predicting $\log(K_s)$ (RMSE no better than 0.5) (Jaynes and Tyler, 1984; Ahuja et al., 1989; Tietje and Hennings, 1996; Donatelli et al., 2004).

5.6 Numerical Methods

Numerical methods can be used to solve the Richards equation under conditions where analytical solutions do not exist. These methods were first applied to soil water movement in the early 1960s (Ashcroft et al., 1962; Hanks and Bowers, 1962). The two most common methods are *finite differences* and *finite elements* (Huyakorn and Pinder, 1983; Smith, 1985). For 1D flow, the first step is to discretize the soil profile into a number of depth intervals Δz. The point at which intervals join is called a *node*. Time is also discretized by intervals Δt. The depth and time intervals can vary. A set of algebraic equations is developed that include the pressure head or water content at each node at a given time level. This leads to a system of *simultaneous equations* that can be solved to find the pressure head or water content using matrix algebra at each time level. The method can be applied to 2D and 3D problems in which case, spatial discretization leads to a grid.

Commonly used numerical models that solve the Richards equation to simulate water flow in variably saturated soils are shown in Table 5.4. In the following sections, HYDRUS-1D and HYDRUS (2D/3D) are used to illustrate important transient flow processes.

5.7 Infiltration

Infiltration is a key process because it determines how much water from rainfall, irrigation, or a contaminant spill enters the soil and how much becomes runoff. It is also important in erosion since there can be no erosion without runoff to transport and scour sediment. In this section, we describe infiltration into a uniform soil, the effect of soil crusts and subsurface layers, infiltration equations, infiltration from a borehole, and subsurface irrigation.

5.7.1 Infiltration into a Uniform Soil

In this example, HYDRUS-1D is used to simulate infiltration into a uniform soil with the hydraulic properties of the Ap horizon of a Cecil sandy loam soil in Georgia (Table 5.5). The water retention parameters were obtained by fitting the van Genuchten (1980) equation to the data from Bruce et al. (1983) using the RETention Curve (RETC) optimization software (van Genuchten et al., 1991). See Radcliffe and Šimůnek (2010) for more details.

Infiltration once ponding starts at the surface is simulated. Therefore, the surface boundary condition for infiltration after ponding occurs (with no surface storage) is a pressure head at the soil surface equal to zero (Dirichlet or type-1 boundary condition):

$$h(0, t) = 0. \tag{5.39}$$

It is assumed that there is no flux (Neumann or type-2 boundary condition) at the bottom boundary ($z = -250\,\text{cm}$):

$$J_w(-250, t) = 0. \tag{5.40}$$

For initial conditions, the soil profile has a pressure head of $-100\,\text{cm}$ at all depths:

$$h(z, 0) = -100. \tag{5.41}$$

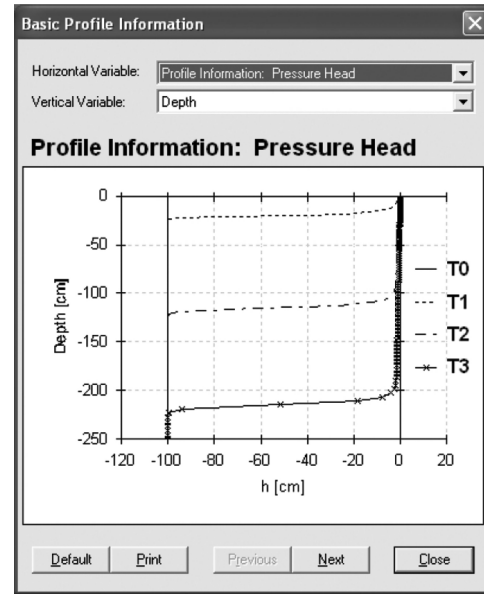
The numerical solution is used to plot profile distributions of pressure head for different times after water began to pond at the surface of a soil during an infiltration event. These are shown in Figure 5.10 for various times. During infiltration, a wetting front


FIGURE 5.10 Pressure heads as a function of depth for various times during infiltration into a uniform loamy sand; $T0 = 0.0\,\text{h}$, $T1 = 0.1\,\text{h}$, $T2 = 1.0\,\text{h}$, and $T3 = 2.0\,\text{h}$.

of higher pressure heads moves down through the soil over time. For a given soil, the abruptness of the wetting front will depend on the shape of the $\theta(h)$ and $K(h)$ functions. Both of these depend on pore-size distribution. For coarse-textured soils with a narrow pore-size distribution, the wetting front will be more abrupt; in a fine-textured soil, the wetting front will be more diffuse. In this case, the wetting front is very sharp as one might expect in a loamy sand. The wetting front is a combination of new water added by the rain and old water displaced to lower depths.

The numerical solution can also be used to estimate the infiltration rate $i(t)$ as a function of time. The infiltration rate is the water flux at the soil surface, so it is described by the Buckingham–Darcy equation for the flux at the surface:

$$i(t) = -J_w(t)\big|_{z=0} = \left[K(h)\frac{\partial h}{\partial z} + K(h) \right]\bigg|_{z=0}, \tag{5.42}$$

where the vertical bar and subscript indicates that the flux is evaluated at the soil surface.

FIGURE 5.11 Infiltration rate as a function of time in a uniform loamy sand.

The infiltration rate is shown in Figure 5.11. It decreases with time and approaches an asymptotic minimum infiltration rate. Experimental observations confirm that $i(t)$ follows the pattern in this figure. This is for a uniform soil with no layers or crusting at the surface and relatively wet antecedent water contents. Equation 5.42 can be used to understand this pattern. When infiltration first starts, the wetting front is steep and very close to the surface (Figure 5.10). As a result, $\partial h/\partial z$ at the surface is large and the first term in Equation 5.42 produces a large value for $i(t)$. Under these conditions, the gradient in pressure head (due mainly to capillarity) is responsible for the rapid movement of water into a moist soil. The second term in Equation 5.42 represents the effect of gravity and may have little effect on water movement during the initial stages of infiltration. Later in the infiltration event, the wetting front has moved deeper into the soil (Figure 5.10). As a result, $\partial h/\partial z$ at the surface is much smaller (maybe even zero) and the first term in Equation 5.42 (and capillarity) has little effect. When the first term approaches zero, $i(t) \approx K_s$ and only gravity causes flow. Under these circumstances, a minimum infiltration rate is reached and it is approximately the saturated hydraulic conductivity of the Cecil Ap horizon, 19.19 cm h^{-1} (Table 5.5), as demonstrated in Figure 5.11.

Because the initial high infiltration rate in a dry soil is due to the pressure head gradient term, if the soil is wetter before the rainfall event, the initial infiltration rate will be lower. However, the final infiltration rate in both a wet and a dry soil will be the same, approximately K_s.

Cumulative infiltration $I(t)$ (L) is the integral of the infiltration rate:

$$I(t) = \int_{0}^{t} i(t)\,dt. \qquad (5.43)$$

It is the area under the rate curve in Figure 5.11. Once the infiltration rate becomes constant, cumulative infiltration increases linearly.

To get a more realistic simulation, one can specify slightly different initial and boundary conditions. For the surface boundary condition, a system-dependent boundary condition (see Equations 5.34 and 5.35) is used that starts with a flux equal to a rainfall rate of 25 cm h^{-1}. When the soil near the surface wets up sufficiently that the pressure head at the first node reaches 0 (h_S in Equation 5.35), the boundary condition changes to a constant-pressure-head boundary condition equal to 0 (ponding with no surface storage). For the bottom boundary condition, a constant-pressure-head boundary condition of zero is used to represent a water table at a depth of 250 cm. For the initial conditions, a pressure-head distribution starting with −250 cm at the soil surface and increasing linearly to the pressure head of 0 cm at the bottom of the model space is specified. This represents a soil profile where the pressure heads are in equilibrium with a water table at a depth of 250 cm.

The simulated distribution of pressure heads as a function of depth for various times are shown in Figure 5.12. The initial equilibrium distribution of pressure heads is apparent. The movement of a wetting front down the profile is also apparent with the front reaching a depth of about 200 cm at the end of the simulation. Compare this figure with the earlier example of infiltration into the same soil with an initial distribution of pressure heads equal to a constant −100 cm (Figure 5.10). The results are similar except for the initial distribution of pressure heads.

The simulated infiltration rate as a function of time is shown in Figure 5.13. Infiltration is a constant flux equal to 25 cm h^{-1} until about 0.2 h and then decreases to a steady rate of 19.19 cm h^{-1}, which is K_s for the soil. The effect of the system-dependent boundary condition at the surface is apparent when this
FIGURE 5.12 Resulting pressure head distributions in the infiltration example with an equilibrium initial distribution of pressure heads: $T0 = 0.0\,h$, $T1 = 0.1\,h$, $T2 = 1.0\,h$, and $T3 = 2.0\,h$.
FIGURE 5.13 Infiltration rate as a function of time in the infiltration example with a system-dependent boundary condition.

figure is compared to the earlier infiltration example (Figure 5.11). With the rainfall rate of 25 cm h^{-1}, once the infiltration rate for the soil drops below this rate, water starts to run off (assuming that surface storage is negligible). In the earlier example, we assumed that water was ponded at the surface from the beginning of the infiltration event. It would take a very high-intensity rainfall event to cause ponding early in the event (more than 40 cm h^{-1}, see Figure 5.11). The system-dependent boundary condition used in this example is more realistic.

5.7.2 Soil Crusts and Subsurface Layers

Another factor that can cause the infiltration rate to decrease is the formation over time of a *surface seal* or *crust* at the soil surface. A surface seal is a very thin layer (1–5 mm) at or just below the soil surface that forms due to the breakdown of soil aggregates and chemical dispersion of clay particles under raindrop impact. The clay particles fill the soil pores and create a layer with a saturated hydraulic conductivity several orders of magnitude less than the undisturbed soil (Miller and Radcliffe, 1992). This low-conductivity layer can prevent saturation of the soil just beneath the seal due to the suction that occurs at the interface (see Section 5.2.3), further reducing the infiltration rate.

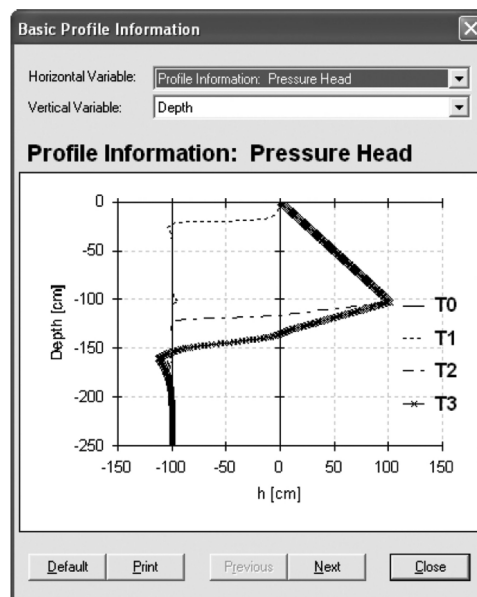
Subsurface clay layers near the surface can also reduce infiltration rates. An unstructured clay layer will usually have a lower K_s than an overlying sand layer and reduce K_{eff} (Equation 5.3) and $i(t)$ once the wetting front enters the clay layer. Again, HYDRUS-1D can be used to plot distributions of pressure heads and water contents in a soil profile that consists of the various horizons of a Cecil sandy loam soil in Georgia (Bruce et al., 1983; Table 5.5). The boundary and initial conditions are the same as in the first infiltration example for a uniform soil (Equations 5.39 through 5.41). The pressure heads at various times are shown in Figure 5.14. The curves are remarkably different from Figure 5.10 for a uniform soil, due primarily to the presence of positive pressures that have peak values at a depth of 100 cm after 1 h. This depth corresponds to the top of the Bt2 horizon. This horizon and the horizons below it have sharply lower K_s than the horizons above (Table 5.5).


FIGURE 5.14 Pressure heads as a function of depth for various times during infiltration into a layered soil: $T0 = 0.0$ h, $T1 = 0.1$ h, $T2 = 1.0$ h, and $T3 = 4.0$ h.

When the wetting front reaches this horizon, water flow is slowed causing pressure to build above the Bt2 horizon. This produces a larger gradient in pressure head across the lower horizons and compensates to a degree for the low conductivities. At a depth of approximately 160 cm, pressure heads have become more negative than the initial conditions. This is due to the increase in K_s that occurs in the C horizon (Table 5.5).

As noted earlier in Section 5.2.3, under steady saturated flow, pressure heads are distributed linearly with depth within a horizon. In Figure 5.14, the distribution is linear above the wetting front, indicating that θ is constant (saturated) in this region. At the wetting front, the lines curve, indicating that θ is changing over time in this region (unsaturated).

The effect of soil layers on the infiltration rate in the layered soil is shown in Figure 5.15. The infiltration rate for a uniform
FIGURE 5.15 Infiltration rate as a function of time in a uniform soil and a layered soil.

soil with the same properties of the first horizon in the layered soil (the curve in Figure 5.11) is included for comparison purposes. Initially, the infiltration rates are the same, but once the wetting front reaches the second (BA) horizon after about 0.2 h, the infiltration rate in the layered soil decreases. This is due to a pressure head gradient at the soil surface that opposes infiltration (Figure 5.14) caused by the lower K_s in the BA horizon. A more severe drop in the infiltration rate occurs after about 0.4 h when the wetting front reaches the Bt2 horizon. After entering this horizon, the infiltration rate in the layered soil approaches a constant value. Thus, layers have an effect on the infiltration rate at the surface through their effect on movement of the wetting front.

A dry coarse-textured layer under a fine-textured layer will also impede deeper movement of the wetting front and reduce the infiltration rate but through a different mechanism. To illustrate this problem, a 2D water flow model, HYDRUS (2D/3D), is used for a soil profile consisting of a clay loam layer to a depth of 20 cm, underlain by a sand layer that extends to a depth of 50 cm. The van Genuchten (1980) hydraulic parameters are taken from the textural class averages of Carsel and Parrish (1988) (clay loam: $\theta_r = 0.095$, $\theta_s = 0.41$, $\alpha = 0.019\,cm^{-1}$, $n = 1.31$, $K_s = 0.26\,cm\,h^{-1}$, and $l = 0.5$; sand: $\theta_r = 0.045$, $\theta_s = 0.43$, $\alpha = 0.145\,cm^{-1}$, $n = 2.68$, $K_s = 29.7\,cm\,h^{-1}$, and $l = 0.5$). The model region is 100 cm in width and a point source of water (as might occur with drip or furrow irrigation) is placed at a distance of 50 cm from the left side ($h_0 = 0$). The initial pressure heads are −500 cm everywhere.

The distribution of water contents 10 h after the point source of water is started is shown in Figure 5.16. The location of the sand layer is apparent in that it has a lower water content ($\theta = 0.05\,cm^3\,cm^{-3}$) under the initial pressure head than the clay loam layer ($\theta = 0.25\,cm^3\,cm^{-3}$). At this early time, the wetting front has not reached the sand layer and the wetting front is semicircular in shape.

The distribution of water contents after 24 h is shown in Figure 5.17. The wetting front has become distorted because water cannot enter the dry sand layer. The reason for this is that pressure heads at the leading edge of the wetting front are negative and water cannot enter the smallest air-filled pores in the sand layer until pressure heads increase to the point where capillarity will draw water into these pores (the water entry pressure head for the sand). This stalls the wetting front until pressure heads rise to the critical level for entry. Since the pore-size distribution is narrower in the sand, it is not long after water first enters the sand that the pressure is high enough at the wetting front to fill the largest capillary pores in the sand. Once the sand is saturated, it no longer impedes flow because K_s is high in the sand compared to the clay layer above. Baver et al. (1972) referred to the action of a buried dry sand layer in temporarily impeding water flow and infiltration as a *check valve*. This principle is used in the design of golf greens, which have a sand surface layer over a coarse gravel layer at about 50 cm. The gravel layer prevents drainage from the root zone under frequent light irrigations, but if there is a heavy rain, the gravel layer will fill and drain the root zone, so that the green does not become waterlogged.

5.7.3 Infiltration Equations

Because of the importance of the infiltration process, simplified solutions to the Richards equation have been developed to predict infiltration. Most of the infiltration equations have been developed for conditions when rainfall does not limit infiltration. In this case, the infiltration rate is less than the rainfall or irrigation rate and runoff occurs. Soil hydraulic properties control the infiltration rate so it is *profile controlled* (Hillel, 2004), also called ponded infiltration, although the depth of ponding may be negligible if surface storage is small. Two examples are shown that represent very different approaches: the Green and

Ampt (1911) equations and the curve number (CN) method. Many infiltration equations have been developed including those by Kostiakov (1932), Horton (1940), Philip (1957), and Parlange et al. (1985).

5.7.3.1 Green–Ampt Equations

Green and Ampt (1911) developed a simplified mechanistic equation for infiltration by assuming that the wetting front in a soil was a square wave or sharp front. Although this is approximately true only in coarse-textured soils, there is no error in predicting the infiltration rate as long the amount of water behind the predicted square front is equal to the amount of new water behind the true wetting front.

The Green–Ampt equation for cumulative infiltration in a uniform soil, including the effect of gravity, is:

$$I(t) = K(h_0)t + \Delta h \Delta \theta \ln \left(1 + \frac{I(t)}{\Delta h \Delta \theta} \right), \qquad (5.44)$$

where

$$\begin{aligned} \Delta \theta &= \theta_0 - \theta_i, \\ \Delta h &= h_0 - h_f, \end{aligned} \qquad (5.45)$$

where

θ_i is the initial water content
θ_0 is the water content at the surface

The pressure head h_0 corresponds to the water content θ_0. The pressure head h_f is the pressure head at the wetting front. Under ponded conditions, θ_0 and $K(h_0)$ can be approximated by θ_s and K_s, respectively, and h_0 can be assumed to be zero (for negligible ponding) or the depth of ponded water. The unknowns in

Equation 5.44 are then $I(t)$ and h_f. White and Sully (1987) showed that the wetting front pressure head can be approximated using the macroscopic capillary length λ_c (Tables 5.1 and 5.2):

$$h_f = -\frac{\lambda_c}{2b}, \qquad (5.46)$$

where b is a dimensionless factor that has a theoretical range of $1/2$ to $\pi/4$ but can be assumed to be equal to 0.55 in most cases (Warrick and Broadbridge, 1992). Hence, the only unknown in Equation 5.44 is $I(t)$, but the equation cannot be solved directly for this variable because it appears both inside and outside the natural log function. Therefore, it must be solved iteratively. Alternatively, Equation 5.44 can be solved for t and the times corresponding to a range of values for cumulative infiltration can be calculated. In contrast to White and Sully (1987), Haverkamp et al. (1985) found that it was best to consider h_f a fitting parameter.

Once the cumulative infiltration curve as a function of time is known, the infiltration rate can be calculated as the instantaneous slope of this curve:

$$i(t) = \frac{dI(t)}{dt}. \qquad (5.47)$$

5.7.3.2 CN Approach

The CN method is an empirically determined rainfall–runoff relationship that provides an indirect estimate of the total depth of water that infiltrates during a storm (McCuen, 1982; NRCS, 2004). It does not give the infiltration rate $i(t)$ but simply the cumulative runoff R at the end of the storm. The method is based on numerous measurements of runoff for many soil types and considers soil texture, soil drainage class, antecedent moisture

conditions, and vegetative cover. The total runoff (*R* in cm) during an event is as follows:

$$R = \frac{(P - 0.2S)^2}{P + 0.8S}, \quad P > I_a, \quad R = 0, \quad P \leq I_a, \qquad (5.48)$$

where

> *P* is the total precipitation in cm
> *S* is the *water storage capacity* of the soil in cm
> I_a is the *initial abstraction* in cm

The water storage capacity is calculated using the CN:

$$S = \frac{2540}{\text{CN}} - 25.4. \qquad (5.49)$$

CNs are tabulated in Chapter 9 of *The National Engineering Handbook* (NRCS, 2004) and vary with land use, ranging from near 0 for a dry, fully vegetated, highly permeable surface to near 100 for an impervious surface. The CN method assumes that an initial amount of rain must occur before runoff starts and this is called the initial abstraction I_a, which is assumed to be equal to 0.2*S*. Runoff is zero until precipitation exceeds I_a (see Equation 5.48).

The CN also varies with the soil hydrologic group, which ranges from Group A (soils with low runoff potential when thoroughly wet) to Group D (soils with high runoff potential when thoroughly wet). Hydrologic groups are described in Chapter 7 of the *National Engineering Handbook* (NRCS, 2004) and they are also given for all U.S. soil series in the National Soil Information System (NASIS; NRCS, 2009). This information is also available through the Web Soil Survey at http://websoilsurvey.nrcs.usda.gov/app. The CN can be adjusted for antecedent runoff conditions I through III, representing dry, normal and wet conditions but some studies have found that this does not improve the predictions (see Chapters 9 and 10, NRCS, 2004). With the CN approach, there is an emphasis on management and cover. This is a recognition of the importance of crusting (and impervious surface percentage) on infiltration. The use of soil hydrologic groups is also a recognition of the importance of the soil profile (e.g., subsurface impeding horizons), not just the hydraulic properties of the surface layer.

A distinction can be made between *infiltration-excess runoff* and *saturation-excess runoff* (Beven, 2001). Infiltration-excess runoff occurs when downward movement of water into the soil is less than the rainfall rate. This is also called Hortonian flow after Horton (1933). This type of process is described by the Green–Ampt (1911) equations. Saturation-excess runoff occurs when water moves laterally within the soil during a storm and causes lower hillslope positions to be saturated, thereby decreasing the infiltration rate to less than the infiltration capacity. This is also called the *variable-source-area* concept (Hewlett and Troendle, 1975) because the area where runoff occurs expands with the size of the storm as the soil landscape becomes wetter. The CN approach can be considered a saturation-excess approach (Steenhuis et al., 1995). Another way to look at the difference between these processes is to consider the gradients and conductivities (components of Darcy's law, see

Equation 5.42). In infiltration-excess runoff, there is a large gradient favoring infiltration, but the soil conductivity is not sufficiently high to prevent runoff. In saturation-excess runoff, the conductivity may be very high, but the gradient is low or even favors exfiltration (a seep). A final distinction is that the infiltration-excess approach is essentially a 1D (vertical) view of the infiltration process. The saturation-excess approach is a 3D view.

5.7.4 Borehole Infiltration

Infiltration from a borehole is a 3D flow problem (see Figure 5.8). It can be modeled in two dimensions, however, using cylindrical coordinates available in HYDRUS (2D/3D).

Infiltration is simulated from an unlined borehole with a constant head of water into a loamy sand. The van Genuchten (1980) hydraulic properties are taken from the Rosetta Lite database in HYDRUS: $\theta_r = 0.049$, $\theta_s = 0.39$, $\alpha = 0.0347 \, \text{cm}^{-1}$, $n = 1.75$, and $K_s = 4.38 \, \text{cm h}^{-1}$. Since infiltration from a borehole will be symmetrical around the vertical centerline of the borehole (in the absence of any slope or heterogeneities in the soil surrounding the borehole), a 2D slice through the soil from the centerline of the borehole on the left radiating out into the soil to the right is simulated. The horizontal dimension of the model space is 100 cm and the vertical dimension is also 100 cm with the soil surface at the top (Figure 5.18). A borehole with a radius of 5 cm penetrates to a depth of 30 cm below the soil surface. The boundary condition at the bottom of the model space (at a depth of 100 cm below the soil surface) is a free-drainage boundary condition simulating a deep water table (see Section 5.4.1.3). To simulate water ponded in the borehole to a height 10 cm above the bottom of the borehole, a constant-head boundary condition is used. Along the boundary representing the bottom of the borehole and up the side wall to a height of 10 cm, the boundary condition is a constant pressure head of 10 cm in equilibrium with the lowest nodal point on this boundary. This ensures that the pressure at the bottom of the borehole is 10 cm and pressure decreases linearly up the side wall to a value of 0 at 10 cm above the borehole bottom. All other points along the model-space boundary are a no-flux boundary condition. The distribution of pressure heads after 3 h of simulation are shown in Figure 5.18. Capillarity has drawn the wetting front into the soil in all directions including upward toward the soil surface. The influence of gravity is most apparent in the saturated region immediately surrounding the ponded portion of the borehole where a teardrop shape to the contour is apparent.

The infiltration rate from the borehole as a function of time is shown in Figure 5.19. The volumetric infiltration rate (*Q* in cm^3 h^{-1}) has been converted to the infiltration flux (*i* in cm h^{-1}) by dividing by the bottom area of the borehole (πr^2). The infiltration rate declines to a near-steady value within one-half hour, much like 1D infiltration into a uniform soil with water ponded at the surface (see Figure 5.11). Unlike 1D infiltration, however, the steady value in the borehole infiltration example is much greater than the soil K_s (4.38 cm h^{-1}). This is because flow is occurring in three dimensions (Darcy's law for 1D flow does not apply) and because the gradient is much more than a unit gradient. This is why the borehole equation (Equation 5.22) must be used to calculate K_s.
FIGURE 5.18   Distribution of pressure heads after 3 h in the borehole infiltration example.
FIGURE 5.19   Infiltration rate as a function of time in the borehole infiltration example.

5.7.5 Subsurface Irrigation

Irrigation using a buried irrigation line results in flow of water that can be modeled as 2D infiltration. Skaggs et al. (2004) compared measured water contents in a Hanford sandy loam soil with those simulated using HYDRUS-2D. Soil properties were estimated using the Rosetta database for van Genuchten (1980) parameters (θ_r = 0.021, θ_s = 0.34, α = 0.023 cm^{-1}, n = 1.4, K_s = 1.6 cm h^{-1}, and l = −0.92). The irrigation line was buried at a depth of 5 cm. The model space consisted of a 2D soil block, 50 cm wide and 60 cm deep with the soil surface at the top (Figure 5.20). It was assumed that water flow would be
FIGURE 5.20   Distribution of water contents around a subsurface irrigation line after 10 h. (From Skaggs, T.H., T.J. Trout, J. Šimůnek, and P.J. Shouse. 2004. Comparison of HYDRUS-2D simulations of drip irrigation with experimental observations. J. Irrigat. Drain. Eng. 130:304–310.)

symmetrical about the vertical centerline of the irrigation pipe so only half the area around the pipe was simulated. All of the boundaries were considered to be zero-flux except for a 2-cm diameter semicircle on the left boundary, which represented the irrigation line. The boundary condition on this semicircle was specified as a flux of 6.37 cm h^{-1} (the irrigation rate in cm^3 h^{-1} for a given segment of irrigation line divided by one-half the surface area of the irrigation line segment). Water contents are shown after 10 h of simulated irrigation in Figure 5.20. The wetting front has moved out in a nearly cylindrical manner due to capillarity but some distortion of the wettest contour due to gravity is apparent. The HYDRUS simulations agreed quite well with the measured distributions of water contents (Skaggs et al., 2004).

5.8 Redistribution

Once a rainfall event is over, water movement does not cease. For example, the final distribution of pressure heads in Figure 5.12 will continue to change after 2 h even if there is no further precipitation. This process is known as *redistribution* or drainage (Jury and Horton, 2004). In theory, with a water table at a depth of 250 cm, pressure heads will return to the initial distribution of an equilibrium profile with pressure heads increasing linearly from −250 cm at the surface to 0 cm at the water table (Figure 5.12). In reality, it takes so long for redistribution to occur that an equilibrium profile rarely occurs unless the water table is at a very shallow depth. To see this, the previous infiltration simulation shown in Figure 5.12 is extended to 1 week (168 h) with no precipitation (or evapotranspiration) beyond 2 h using HYDRUS-1D.

The resulting pressure head distribution is shown in Figure 5.21. The pressure head at time $T1 = 2$ h shows the depth to
which the wetting front moved (about 200 cm) during the rainfall event and is the last time in the earlier infiltration example (Figure 5.12). It is clear that pressure heads continued to change beyond 2 h with pressure heads decreasing at more shallow depths. The curves are moving in the direction of the equilibrium distribution (the initial conditions in Figure 5.21), but even after a week of redistribution they are far from a true equilibrium distribution. This is because as pressure heads decrease at shallow depths, unsaturated hydraulic conductivity decreases and water movement is slower. The average pressure head in the profile after about a week is close to −100 cm, which is the pressure head often used to estimate field capacity in coarse-textured soils (Romano and Santini, 2002).

5.9 Evaporation

Evaporation is the reverse process of infiltration: a flux *out of* the soil at the surface. HYDRUS-1D is used to illustrate this process with the same loamy sand employed for the borehole example ($\theta_r = 0.049$, $\theta_s = 0.39$, $\alpha = 0.0347$ cm^{-1}, $n = 1.75$, and $K_s = 4.38$ cm h^{-1}, $l = 0.5$). The surface boundary condition is a system-dependent boundary condition for evaporation: an evaporative flux of 1 cm day^{-1} (0.042 cm h^{-1}) until the surface dries to a pressure head of −15,000 cm ($E = 0.042$ cm h^{-1}, $h_A = -15,000$ cm, see Equations 5.34 and 5.35). At that time, the boundary condition switches to a constant pressure head of −15,000 cm. The resulting water content profiles for different times after evaporation started are shown in Figure 5.22.

The numerical solution shows that water contents decrease with depth as time progresses due to the loss of water through evaporation at the surface. Instead of a wetting front seen in

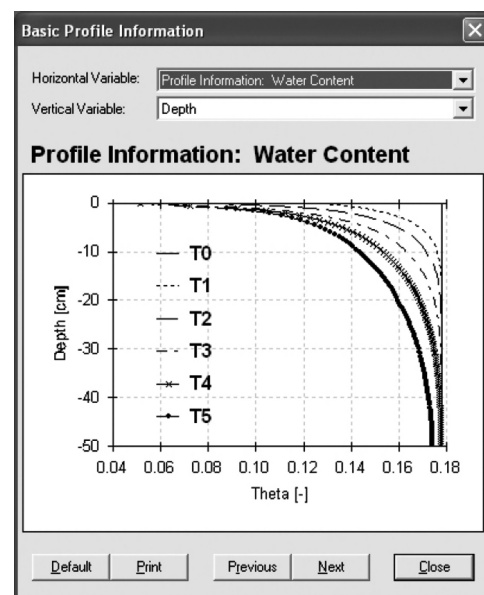
FIGURE 5.21 Simulated pressure head distributions in the redistribution example: $T0 = 0$ h, $T1 = 2$ h, $T2 = 84$ h, $T3 = 126$ h, and $T4 = 168$ h.


FIGURE 5.22 Water contents as a function of depth for various times during evaporation from a uniform loamy sand: $T0 = 0$ h, $T1 = 3$ h, $T2 = 6$ h, $T3 = 12$ h, $T4 = 24$ h, and $T5 = 48$ h.
FIGURE 5.23 Evaporation rate as a function of time in a uniform loamy sand.

the infiltration example, in this case, a drying front progresses deeper into the soil. The evaporation rate for the same soil is shown in Figure 5.23. Evaporation is high initially and constant. During this period, evaporation from the soil is able to keep up with the potential evaporation rate of 0.042 cm h^{-1}. The reason for the high initial evaporation rate is the steep gradient in water potential between the wet soil and the dry air above the soil and the high hydraulic conductivity of the wet soil surface layer (Figure 5.22). During this period, the decrease in the hydraulic conductivity of the surface layer is fully compensated by the increase in the hydraulic gradient. This period is referred to as *stage one* evaporation (Hillel, 2004). After about 10 h, the evaporation rate starts to drop. At this point, the soil surface has dried completely (reached the minimum pressure head of −15,000 cm) and the actual evaporation rate becomes less than the potential rate. The evaporation rate decreases with time because the hydraulic gradient at the surface gradually decreases. This period of decreasing evaporation rate is referred to as *stage two* evaporation. Eventually, the evaporation rate approaches a constant residual rate where most of the flux at the surface is in the vapor phase. This final period is referred to as *stage three* evaporation.

The heat and radiant energy balance at the soil surface determines the potential evaporation rate ET_0. This varies from day-to-day and even minute-to-minute as wind speed, radiation, and relative humidity change. The actual evapotranspiration rate ET is usually less than ET_0. Part of the evapotranspiration demand is satisfied by soil evaporation. As can be seen in Figure 5.23, evaporation can be high when the soil is wet (e.g., shortly after a rainfall event) but rapidly drops to a very low rate. Thus, evaporation alone usually will not meet the potential evapotranspiration demand ET_0.

5.10 Transpiration

5.10.1 Soil–Plant–Atmosphere Continuum

Where nondormant plants are present, most of the evaporative demand is satisfied by transpiration. Photosynthesis uses only about 1% of the water transpired by plants (Hillel, 2004).

For photosynthesis to occur, however, CO_2 must enter the plant leaves and reach chloroplasts. As a result, plants must maintain open stomata, which allow CO_2 to enter the interior of leaves (Figure 5.1). Plant cells must be moist to function so the open stomata result in a continuous loss of water from the interior of the leaf through the stomata due to evaporation. This water must be replenished by plant uptake of water through the root system or the plant leaf cells will desiccate and the plant will wilt.

Water moves through the plant to the atmosphere along a continuous path. This is called the *soil–plant–atmosphere continuum* (Philip, 1966). Water moves from the soil across the plant root to the xylem vessels. It then moves up the xylem vessels to the plant leaves. In the leaves, water exits the xylem vessels and moves through leaf cells to the stomatal cavities where it evaporates. A steady gradient of decreasing water potential pulls water from the soil through the plant to the atmosphere. Water is drawn first from the surface horizons where roots are more numerous. As this water is depleted, a plant draws water from deeper in the soil, but this requires more of an energy gradient due to the effect of gravity. Also root densities (length of root per volume of soil) decrease with depth.

There is a limiting leaf-water potential, below which stomatal guard cells begin to lose turgor and close. As soon as this happens, the actual evapotranspiration rate drops below the potential rate: $ET < ET_0$. Stomata can be partially closed, which reduces transpiration but does not completely stop it. If stomata close completely then $ET = 0$.

5.10.2 Root Water Uptake

Root water uptake can be considered a sink term in the Richards equation (Equation 5.26). Various terms have been developed including those by Molz (1981), Jarvis (1989), and Vrugt et al. (2001). Feddes et al. (1978) modeled root water uptake as a function of soil water pressure head h:

$$S(h) = \alpha(h)S_p, \qquad (5.50)$$

where

$S(h)$ is the root water uptake or volume of water removed from a unit volume of soil per unit time (T^{-1})

S_p is the potential water uptake rate (T^{-1})

$\alpha(h)$ is a dimensionless stress response function of the pressure head ($0 \leq \alpha \leq 1$)

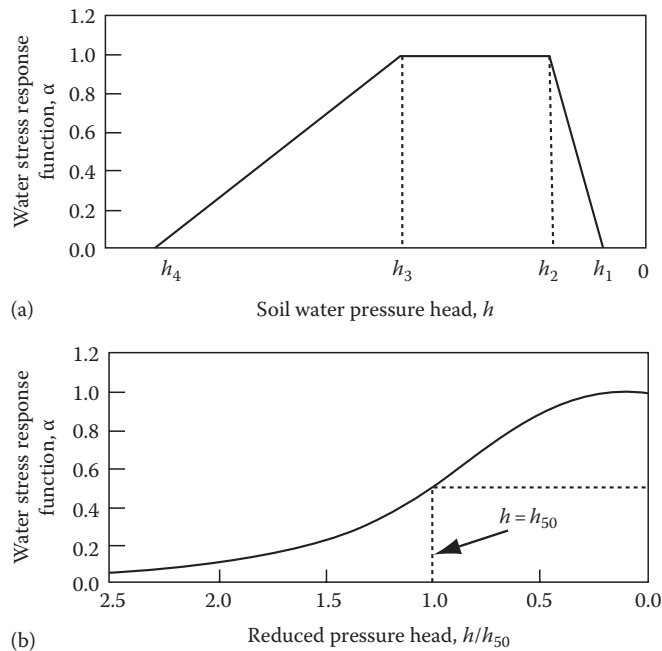
The stress response function is shown in Figure 5.24a. Water uptake is assumed to be 0 close to saturation due to a lack of oxygen in the root zone (pressure head greater than h_1). For a pressure head less than h_4 (the wilting-point pressure head), water uptake is also assumed to be zero. Water uptake is optimal between pressure heads of h_2 and h_3. The pressure head h_3 may be adjusted depending on the transpiration rate so that it is more negative when transpiration rates are low (optimal root water uptake occurs over a wider range in pressure head at lower transpiration rates).


FIGURE 5.24 Plant-water stress response function $\alpha(h)$ as used by (a) Feddes et al. (1978) and (b) van Genuchten (1987).

FIGURE 5.25 Precipitation (a negative surface flux) as a function of time in the transpiration example.

Van Genuchten (1987) suggested an *S*-shaped root water stress response function (Figure 5.24b). The parameter h_{50} represents the pressure head at which root water uptake is reduced by 50% during conditions of negligible osmotic stress. Note that in contrast to the response function of Feddes et al. (1978), this response function does not consider the reduction near saturation due to low oxygen levels. Van Genuchten (1987) also expanded the root water stress response function to include osmotic effects.

HYDRUS-1D can be used to simulate evapotranspiration. The same loamy sand as in the previous examples ($\theta_r = 0.049$, $\theta_s = 0.39$, $\alpha = 0.0347\,cm^{-1}$, $n = 1.75$, and $K_s = 105.12\,cm\,day^{-1}$) is used to simulate plant transpiration. The simulation is run for 1 year using precipitation and potential evapotranspiration from Athens, Georgia, for 1995, when total precipitation was 141 cm (slightly greater than the long-term average of 127 cm). The simulation is for a grass lawn that is not dormant in winter.

A system-dependent atmospheric boundary condition with surface runoff is used for the upper boundary condition to simulate infiltration and evaporation. The free-drainage boundary condition is used to simulate a deep water table for the lower boundary condition (see Section 5.4.1.3). The Feddes et al. (1978) water uptake reduction model (Equation 5.50) is used with threshold pressure heads appropriate for grass: $h_1 = -10\,cm$, $h_2 = -25\,cm$, $h_3 = -300\,cm$ for high transpiration rates and $-1000\,cm$ for low transpiration rates, and $h_4 = -15,000\,cm$ (see Figure 5.24a). A full canopy is assumed and consequently there is no evaporation. A root distribution that decreases linearly from the soil surface to a depth of 100 cm is specified.

The potential surface flux as a function of time is shown in Figure 5.25. Since there is no evaporation, the only potential surface flux is precipitation, so this is a plot of daily rainfall
(as negative fluxes) for 1995 in Athens, Georgia. There is a dry period in early spring and there are large rainfall events in the early fall.

Potential and actual evapotranspiration (root water uptake in this case) are shown in Figure 5.26. It is clear that potential evapotranspiration is low during the winter months and reaches peak values of nearly 1 cm day^{-1} in summer. Actual evapotranspiration is identical to potential evapotranspiration until about day 80 when the first dry spell starts. At this point, actual transpiration drops below the potential rate due to plant-water stress and remains below the potential rate for much of the summer. In the fall, when potential evapotranspiration rates decrease and the soil profile water contents start to increase, actual and potential evapotranspiration rates again coincide.

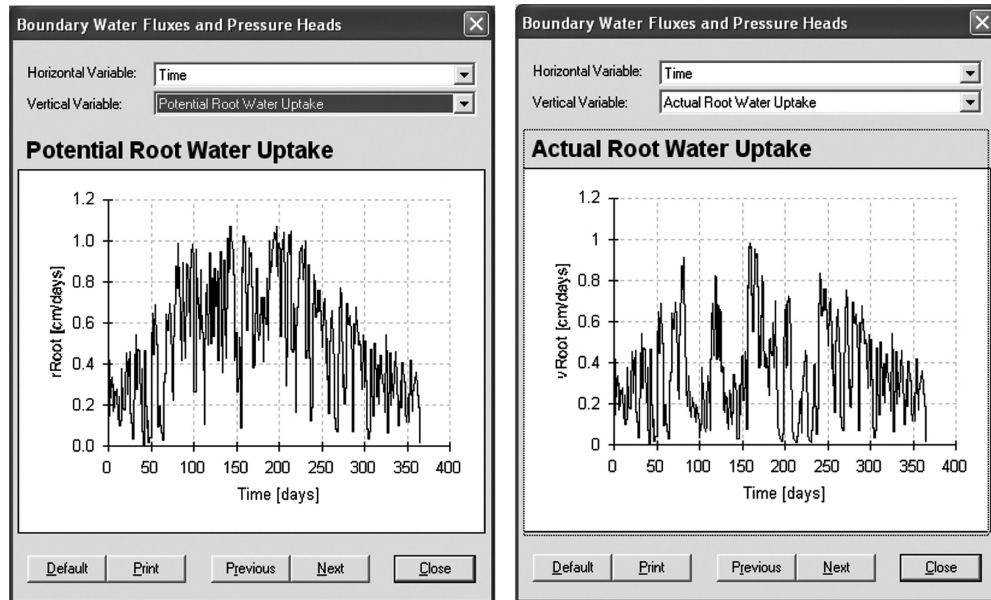
The pressure head at a depth of 5 cm is shown in Figure 5.27. When the first dry period occurs in the early spring, the pressure head at this depth drops quickly to the minimum value of $-15,000\,cm$ (wilting point) due to root uptake. The pressure head at a depth of 50 cm (Figure 5.28) also drops to the wilting point but the drop occurs later. With the rainfall that starts shortly after 100 days, pressure head near the surface recovers, but the pressure head at 50 cm remains at wilting point because this rainfall does not penetrate to deeper depths in the soil profile. At about 120 days, there has been sufficient rainfall that pressure heads at both depths return to near zero. However, the pressure head at the deeper depth soon returns to wilting point because water from small rainfall events that keep the shallow depths relatively wet do not penetrate to deeper depths. A higher rainfall period from about 140 to 180 days results in pressure heads near zero at both depths. After about 180 days, the pressure head at the deeper depth returns to wilting point and stays there until the large rainfall event on about day 230.


FIGURE 5.26   Potential root water uptake (left) and actual root water uptake (right) of water as a function of time in the transpiration example.
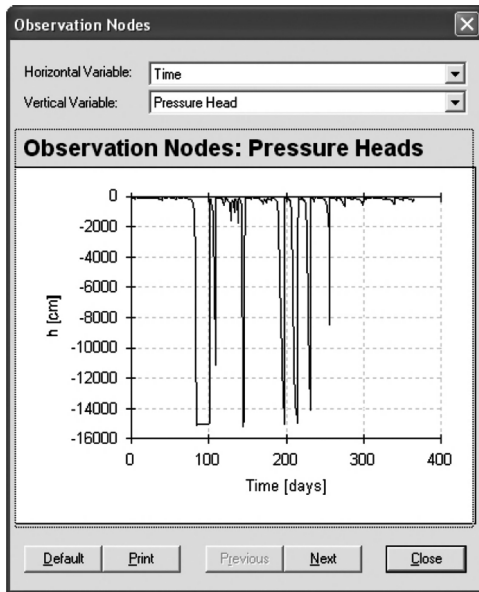

FIGURE 5.27   Pressure head as a function of time at a depth of 5 cm in the transpiration example.

FIGURE 5.28   Pressure head as a function of time at a depth of 50 cm in the transpiration example.

In contrast, the pressure head near the surface responds to the small rainfall events during this interval. Late in the season, a large rainfall event on about day 280 and lower potential evapotranspiration rates result in pressure heads at both depths returning to near zero.

Overall, these results show that even in a slightly wetter than normal year in a region of the United States with relatively high rainfall, this lawn experienced considerable water stress during the summer. This is due in large part to the low plant-available water in such a coarse-textured soil.

5.11 Preferential Flow

Increasing evidence exists that variably saturated flow in many field soils is not consistent with the uniform flow pattern typically predicted with the Richards equations (Quisenberry and Phillips, 1976; Luxmoore, 1981; Flury et al., 1994; Hendrickx and Flury, 2001). This is due to the presence of macropores, fractures, or other structural voids or biological channels through which water and solutes may move preferentially while bypassing a large

part of the matrix pore space. *Preferential flow* and transport processes are probably the most frustrating processes hampering accurate predictions of contaminant transport in soils and fractured rocks. Contrary to uniform flow, preferential flow results in irregular wetting of the soil profile as a direct consequence of water moving faster in certain parts of the soil profile than in others. Hendrickx and Flury (2001) defined preferential flow as constituting all phenomena where water and solutes move along certain pathways while bypassing a fraction of the porous matrix. Water and solutes for these reasons can propagate quickly to far greater depths than would be predicted with the Richards equation describing uniform flow.

The most important causes of preferential flow are the presence of *macropores* and other structural features, development of flow instabilities (i.e., *fingering*) caused by profile heterogeneities or water repellency (Hendrickx et al., 1993), and *funneling* of flow due to the presence of sloping soil layers that redirect downward water flow. While the latter two processes (i.e., flow instability and funneling) are usually caused by textural differences and other factors at scales significantly larger than the pore scale, macropore flow and transport are usually generated at the pore or slightly larger scales, including scales where soil structure first manifests itself (i.e., the pedon scale; Šimůnek et al., 2003).

5.11.1 Macropores

Uniform flow in granular soils and preferential flow in structured media (both macroporous soils and fractured rocks) can be described using a variety of multipermeability models. While *single-permeability* models assume that a single-pore system exists that is fully accessible to water, *dual-permeability* models assume that the porous medium consists of two interacting pore regions, one associated with the interaggregate, macropore, or fracture system, and one comprising the micropores (or intraaggregate pores) inside soil aggregates or the rock-soil matrix.

The simplest formulation for water flow is a single-permeability (equivalent porous medium) model applicable to uniform flow in soils. Other models apply in some form or another to preferential flow or transport. Dual-permeability models are those in which water can move in both the inter- and intraaggregate pore regions (or matrix and fracture domains). These models in various forms are now also becoming increasingly popular (Pruess and Wang, 1987; Gerke and van Genuchten, 1993). They differ mainly in how they implement water flow in and between the two pore regions. Common approaches to calculating water flow in macropores or interaggregate pores use Poiseuille's equation (Ahuja and Hebson, 1992), the Green and Ampt or Philip infiltration models (Chen and Wagenet, 1992), the kinematic wave equation (Germann, 1985), or the Richards equation (Gerke and van Genuchten, 1993). Multipermeability models are based on the same concept as dual-permeability models but include additional interacting pore regions. These models can be readily simplified to the dual-permeability approaches. Recent reviews of preferential flow processes and available mathematical models are provided by Hendrickx and Flury (2001), Šimůnek et al. (2003), and Jarvis (2007).

Another way to simulate the effect of macropores on water flow is through the use of *scaling*. This is a procedure designed to simplify the description of the spatial variability in the soil hydraulic properties. Here, we describe scaling as implemented in the HYDRUS models. It is assumed that variability in the hydraulic properties of a given soil profile can be approximated by means of a set of linear scaling transformations, which relate the soil hydraulic characteristics $\theta(h)$ and $K(h)$ at a point in the soil to reference characteristics $\theta^\star(h^\star)$ and $K^\star(h^\star)$. The technique is based on the similar media concept introduced by Miller and Miller (1956) for porous media, which differ only in the scale of their internal geometry. The concept was extended by Simmons et al. (1979) to materials that differ in morphological properties, but that exhibit scale-similar soil hydraulic functions. Three independent scaling factors are employed in HYDRUS. These three scaling parameters may be used to define a linear model of the actual spatial variability in the soil hydraulic properties as follows (Vogel et al., 1991):

$$K(h) = \alpha_K K^\star(h^\star),$$
$$\theta(h) = \theta_r + \alpha_\theta [\theta^\star(h^\star) - \theta_r^\star],$$
$$h = \alpha_h h^\star,$$

(5.51)

in which, for the most general case, α_K, α_θ, and α_h are mutually independent scaling factors for the hydraulic conductivity, water content, and the pressure head, respectively. Less general scaling methods arise by invoking certain relationships between α_K, α_θ, and α_h. In HYDRUS, scaling factors for each node can be generated stochastically by specifying the mean and standard deviation of the factors. Spatial correlation of the scaling factors can also be included.

As an example of scaling, HYDRUS (2D/3D) is used to simulate infiltration under conditions of incipient ponding of water at the surface into a 2D block of soil 300 cm in width and 100 cm deep. The soil is a loam with hydraulic properties taken from the Rosetta Lite database ($\theta_r = 0.061$, $\theta_s = 0.399$, $\alpha = 0.011$ cm^{-1}, $n = 1.474$, and $K_s = 0.50$ cm h^{-1}). A standard deviation of 1.0 is specified for log α_K with a correlation length 10 times larger in the vertical direction than the horizontal direction. The spatial distribution of K_s for a given realization is shown in Figure 5.29. In this case, the stochastic assignment of scaling factors has produced two zones of high K_s and the larger correlation length in the vertical direction has stretched these zones along the *z*-axis. The distribution of water contents in this soil profile 0.3 h after infiltration began is shown in Figure 5.30. Preferential flow in the two zones causes the wetting front to advance further in these areas.

5.11.2 Fingering and Funnel Flow

Fingering and funnel flow occur in layered soil profiles where a fine-textured layer overlies a coarse-textured layer. Fingering can occur when there is no slope to the coarse-textured layer. In an experiment to examine fingering, Baker and Hillel (1990) used a plexiglass chamber 75 cm wide, 52 cm high, and 1.3 cm thick. The top layer was fine sand with particle sizes between 45 and

106 μm. The sublayer consisted of a coarse-textured sand with a particle-size range that varied from experiment to experiment.

When the wetting front reached the coarse layer, water could not enter because the wetting front pressure head was less than the water entry value for the coarse sublayer (as shown in the HYDRUS simulation in Figure 5.17). The wetting front would pause at the interface and over time the wetting front pressure head would increase. When the wetting front pressure head increased to the value required to enter the smallest pore in the coarse sublayer, water started to infiltrate. Eventually, the wetting front pressure head increased to a value where the flux through the coarse sublayer was equal to or greater than the flux through the top layer. Baker and Hillel (1990) called this the effective water entry value h_e. If the flux was greater through the coarse-textured sublayer than through the fine-textured top layer, then the only way for flow in the two layers to be equal was for water to flow through a fraction of the sublayer in discreet *fingers* (Figure 5.31). The effective water entry value corresponded with the inflection point on the water release curve. This represented the dominant pore size. The fraction of wetted
FIGURE 5.31   Tracings (alternating solid and dashed lines) of wetting front position with time during infiltration in the experiment by Baker and Hillel (1990). The numbers in the figure show the time (minutes) of the wetting fronts. The sublayer in this case consisted of a coarse sand with particle sizes between 500 and 710 μm. (From Baker, R.S., and D. Hillel. 1990. Laboratory tests of a theory of fingering during infiltration into layered soils. Soil Sci. Soc. Am. J. 54:20–30.)
FIGURE 5.32 Schematic of the experimental setup of a plexiglass chamber 180 cm wide, 110 cm tall, and 1 cm thick, filled with fine soil and a discontinuous 15 cm thick coarse layer used by Walter et al. (2000). (From Walter, M.T., J.-S. Kim, T.S. Steenhuis, J.-Y. Parlange, A. Heilig, R.D. Braddock, J.S. Selker, and J. Boll. 2000. Funneled flow mechanisms in a sloping layered soil: Laboratory investigations. Water Resour. Res. 36:841–849.)

soil in the coarse sublayer at steady state was equal to the ratio of the flux through the top layer and $K(h_e)$ in the sublayer.

When the coarse sublayer has a slope, *funneling* occurs. In another experiment, Walter et al. (2000) packed fine sand into a plexiglass chamber 1 cm in thickness with a discontinuous, embedded, layer of coarse sand (Figure 5.32). They investigated the effect of slope and infiltration rate. Different color dyes were applied to intervals at the infiltration surface once steady flow was achieved to show stream lines.

During infiltration when the wetting front reached the coarse layer, it could not enter this layer because the wetting front pressure heads were less than the water entry value, just as shown in the HYDRUS (2D/3D) simulation (Figure 5.17). Since there was a slope to the layer, water funneled laterally to the end of the layer before penetrating deeper into the chamber (Figure 5.33).
FIGURE 5.33 Photograph of an experimental run with an angle of 7.1° and an infiltration rate of 120 mm day⁻¹ by Walter et al. (2000). (From Walter, M.T., J.-S. Kim, T.S. Steenhuis, J.-Y. Parlange, A. Heilig, R.D. Braddock, J.S. Selker, and J. Boll. 2000. Funneled flow mechanisms in a sloping layered soil: Laboratory investigations. Water Resour. Res. 36:841–849.)

Above the coarse layer, pressure head increased at the interface in the downslope direction because more and more water was being diverted. If the infiltration rate was high enough, pressure head reached the water entry value and infiltration occurred before the end of the embedded layer was reached. At the tip of the embedded layer was a toe area where water never infiltrated the coarse layer. This was because the pressure was relieved by flow around the toe. Thus, funneling above sloping coarse layers results in water (and solutes) penetrating only a portion of a soil profile and is therefore a type of preferential flow (Kung, 1990a, 1990b).

5.12 Groundwater Recharge and Discharge

The processes of groundwater recharge, groundwater discharge, the position of the water table, and streamflow are all interrelated in a humid environment (Fetter, 1988). This can be seen by simulating the wetting of an initially dry hillslope using HYDRUS (2D/3D). In this case, the 2D model space is much larger than any of the earlier simulations. The hillslope is 100 m long in the horizontal direction and extends from a ridgetop on the left to a stream channel on the right (Figure 5.34). At the ridgetop, the soil surface is 50 m above the bottom of the model space. At the stream channel, the soil surface is 20 m above the bottom of the model space. The stream channel is 5 m deep (indicated by the nickpoint in Figure 5.34). The soil surface is given a convex shape. The boundary condition at the soil surface is a constant flux of 2 cm day⁻¹. The boundary condition on the left is a no-flux condition appropriate for a ridgetop, where no lateral flow (only recharge) is expected. The bottom boundary condition is also a no-flux condition indicating impermeable rock. The boundary condition beneath the stream channel where no lateral flow (only discharge) is expected is a no-flux boundary condition. The boundary condition at the stream channel is a seepage condition, a type of system-dependent condition discussed previously in Section 5.4.1.3. The initial pressure heads are −100 m everywhere in the hillslope. The hydraulic properties of the hillslope are that of a loam soil textural class in the Carsel and Parrish (1988) database ($\theta_r = 0.078$, $\theta_s = 0.43$, $\alpha = 0.036$ cm⁻¹, $n = 1.56$, and $K_s = 24.96$ cm day⁻¹). The simulation is run for 1000 days.

To do this simulation accurately, so that the short-term response of the hillslope to a rainfall event would produce timely streamflow, would require many more nodes than we have used here (we used 3921). Fiori and Russo (2007) found that a 3D numerical model that included preferential flow was required to simulate the short-term response. Our example used a low-constant flux at the soil surface instead of daily rainfall. We did not include evaporation or root water uptake driven by daily potential evapotranspiration. However, our simulation will be adequate to show the long-term response to wetting.

The distribution of hillslope pressure heads over time are shown in Figures 5.34 through 5.36. After 100 days, a wetting
FIGURE 5.34 Pressure heads after 100 days in the hillslope example.
FIGURE 5.35 Pressure heads after 570 days in the hillslope example.

front of unsaturated pressure heads has moved uniformly downward in the hillslope to a depth of about 5 m (Figure 5.34). After 570 days, the wetting front has reached the bottom of the model space on the right (where the distance from the soil surface is the shortest) and a zone of saturated soil has expanded from the right corner to cover nearly the entire lower region of the hillslope (Figure 5.35). The top of the 0–1 cm pressure head contour represents the water table. The last portion of the

hillslope to wet up is the lower left corner because this region is farthest from the soil surface and the extending wetting zone coming in from the right. On the right boundary, the water table has reached the bottom of the channel so water will start exiting the hillslope through the seep into the stream channel. Further rise in the water table next to the stream channel is limited due to the loss of water to the stream. After 800 days, the water table beneath the ridgetop has risen to a height of
FIGURE 5.36   Pressure heads after 800 days in the hillslope example.

about 35 m above the bottom of the model space (Figure 5.36). On the right, the water table comes very close to the soil surface at about 5 m upslope from the stream channel. The water table at the stream channel has risen to the point that it is about 3 m above the bottom of the channel indicating that the height of water in the stream should be 3 m. There was no further change in the water table from the positions seen for day 800 through the remainder of the simulation (up to 1000 days), indicating that the system has reached a steady state of dynamic equilibrium. The shape of the water table is a subdued replica of the hillslope topography.

In Figure 5.37, the flow through the seepage boundary is shown as a function of time. There is no seepage to the channel

FIGURE 5.37   Seepage flow in the hillslope example.

until about day 500 when the water table intersects the stream channel. The seepage flux increases until about 800 days when it attains a steady value of $2\,m^2\,day^{-1}$, which is the steady infiltration rate through the soil surface (input equals output). At that point, the slope of the water table is such that a sufficient gradient has been generated, given the hydraulic conductivity of the soil that the hillslope can transmit the incoming water at the rate at which it enters the hillslope. Hence, the water table can never be completely flat or there would be no gradient and no flow through the hillslope (unless there is no input). The steepness of the water table will depend on the input and the hydraulic conductivity and length of the hillslope.

The effect of hydraulic conductivity on the slope of the water table can be seen by rerunning the simulation with a saturated hydraulic conductivity that is 10 times the value for the loam in the example so far (249.6 instead of $24.96\,cm\,day^{-1}$). The distribution of pressure heads after 1000 days is shown in Figure 5.38. The water table is nearly flat because only a very small gradient is required to produce the equilibrium flow through the hillslope, given the high K_s in this example. In this case, the shape of the water table is not as reflective of the hillslope topography.

Overall, these results are similar to what was shown earlier in Figure 5.4 in regard to flow to drains. In that simplified analysis of steady flow, it was found that the water table had an elliptical shape and the maximum height of the water table was a function of the infiltration rate at the soil surface, the saturated hydraulic conductivity of the soil, and the distance between the drains (which would correspond to the hillslope length in these examples).

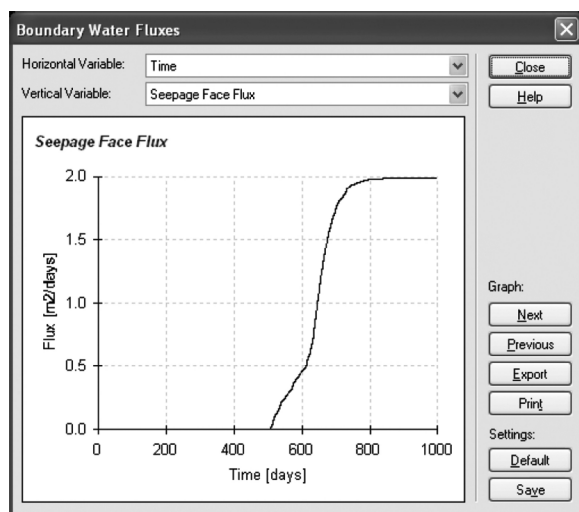
These simulations imply that during wet periods (such as winter months in the eastern United States), the water table will rise to an average height characteristic of the climate and


FIGURE 5.38 Pressure heads after 1000 days in the hillslope example using a saturated hydraulic conductivity 10 times the value for a loam soil.

hillslope hydraulic properties. After a long drought, it may take several winter seasons to reestablish the water table at its equilibrium height, even though water contents at the soil surface are near normal. Stream base flow would not return to normal levels until the equilibrium winter water table was fully established.

The shape of the hillslope can also have important effects. If the surface is changed from a convex to a concave hillslope surface, the water table may rise to the surface at the bottom of the footslope in the concave area. This area can be expected to produce saturation-excess runoff as described earlier in Section 5.7.3. In contrast to the previous examples, the water table will be deeper higher up the hillslope at the *shoulder* position. Daniels and Gamble (1967) noted that the shoulder position in hillslopes with broad ridges and narrow valleys in the coastal plain region of the southeastern United States were drier than other areas in the landscape and produced red soils indicative of oxidized iron (aerobic conditions). Gray soils indicative of reduced iron formed at the base of the hillslope and near the center of the broad ridge. They attributed these soil formation processes, not to differences in parent material but rather to the position of the water table.

5.13 Summary

Soil water movement is a key process that affects both water quantity and quality in our environment. Water movement in soils occurs primarily under unsaturated, transient conditions, but saturated flow and steady-state conditions can occur. Although true steady flow may occur only rarely, transient flow usually approaches steady flow at long times. The governing equations for steady and transient flow are the Darcy and

Richards equations, respectively. The most important hydraulic parameters are the soil saturated hydraulic conductivity and unsaturated hydraulic conductivity function. Laboratory and field methods have been developed to measure these parameters and most of these methods require steady flow conditions. PTFs can be used to predict soil hydraulic properties from more easily measurable surrogate properties, such as soil texture.

Analytical solutions of the Richards equation for soil water flow under unsaturated, transient conditions are very few. Numerical methods such as those implemented in the HYDRUS models are commonly used to solve the equation. Numerical methods can also be used to determine soil hydraulic properties under transient flow conditions in an inverse mode. Simplifications of the unsaturated flow equations have been developed to describe infiltration because of the importance of this transient flow process. However, most of the infiltration equations assume 1D vertical flow and do not account for saturation-excess runoff. Numerical solutions can be used to understand complex soil water processes such as infiltration, evaporation, drainage, transpiration, groundwater recharge, and groundwater discharge. Preferential flow is one of the most challenging aspects of predicting soil water movement but various methods have been developed to account for the effects of macropores, fingering, funnel flow, and spatial variability.

6.1 Introduction

Energy fluxes at soil–atmosphere and plant–atmosphere interfaces can be summed to zero when the surfaces, including plants and plant residues, have no or negligible capacity for energy storage. The resulting energy balance equations may be written in terms of physical descriptions of these fluxes and have been the basis for problem casting and solving in diverse fields of environmental and agricultural science such as estimation of evapotranspiration (ET) from vegetated surfaces, estimation of evaporation from bare soil, rate of soil heating in spring (important for timing of seed germination), rate of residue decomposition (dependent on temperature and water content at the soil surface), and many other problems. The water balances at these surfaces are implicit in the energy balance equations. So, the soil water balance equation, though different from the surface energy balances, is linked to them; a fact that has often been ignored in practical problem solving. In this chapter the energy balances will be discussed first, followed by the water balance in Section 6.3.

Computer simulation has become an important tool for theoretical investigation of energy and water balances at the earth's surface, and for prediction of important results of the mechanisms involved. This chapter will focus more on the underlying principles of energy and water balance processes, and will mention computer models only briefly. More information on computer models that include surface energy and water

balance components can be found in ASAE (1988), Campbell (1985), Richter (1987), Anlauf et al. (1990), Hanks and Ritchie (1991), Pereira et al. (1995), and Peart and Curry (1998) to mention only a few.

6.2 Energy Balance Equation

A surface energy balance is

$$0 = R_n + G + LE + H, \qquad (6.1)$$

where
    R_n is net radiation
    G is soil heat flux
    LE is the latent heat flux (evaporation to the atmosphere) and is the product of the evaporative flux, E, and the latent heat of vaporization, λ
    H is sensible heat flux (all terms taken as positive when flux is toward the surface and in W m^{-2})

Each term may be expressed more completely as the sum of sub-terms that describe specific physical processes, some of which are shown in Figure 6.1. Note that Equation 6.1 may be written individually for soil, plant, and plant residue surfaces. Net radiation includes the absorption and reflection of shortwave radiation
FIGURE 6.1 Water and energy balance components. Water balance components are in black, energy balance components in white. The shared term LE is shaded. Water balance is discussed in Section 6.3.

(sunlight, R_{si}, and the reflected portion, αR_{si}), as well as the emission and reception of longwave radiation ($L\uparrow$ and $L\downarrow$, respectively, Figure 6.1). Soil heat flux involves not only diffusion of heat, G, as expressed by Fourier's law (see Chapter 9) but also convective heat flux, G_{Jw}, as water at temperature T flows at rate J_w into soil at another temperature T'. Evaporation from both soil and plants are examples of latent heat flux; but so also is dew formation, whether it wets the soil surface or plant canopy. Finally, sensible heat flux may occur between soil and atmosphere or between plant and atmosphere, and may be short-circuited between soil and plant, for example, when sensible heat flux from the soil warms the plant. In the next few paragraphs, these fluxes and values they may assume will be illustrated with examples from some contrasting surfaces under variable weather conditions.

Not shown in Figure 6.1 are energy storage due to photosynthesis and that related to temperature and heat capacity of plants. Heat storage in field crops is often ignored as a minor part of the energy balance, but it may not be trivial for forests where heat flux into and out of vegetation can be important, for example, >35 W m^{-2} with heat storage up to 0.3 MJ m^{-2} (Meesters and Vugts, 1996) and >60 W m^{-2} (Haverd et al., 2007). The latter authors included calculation of vegetative heat fluxes and storage in a soil–vegetation–atmosphere transfer model. Photosynthesis is often ignored as a negligible part of the overall energy balance. Further discussion of heat storage and fluxes in vegetation is beyond the scope of this chapter.

Values of the energy fluxes change diurnally (Figures 6.2 through 6.4) and seasonally (Figures 6.5 and 6.6). Regional advection is the large-scale transport of energy in the atmosphere from place to place on the earth's surface. Regional advection events can change the energy balance greatly as illustrated with measurements taken over irrigated wheat at Bushland, Texas (35°11′N Lat; 102°06′W Long) for the 48 h period beginning on day 119, 1992 (Figure 6.2). Total R_{si} was 26.1 and 26.7 MJ m^{-2} on days 119 and 120, respectively; close to the expected maximum
FIGURE 6.2 Energy balance components over irrigated winter wheat at Bushland, Texas.

FIGURE 6.4 Energy balance components for bare Pullman clay loam soil after 35 mm of rain at Bushland, Texas.

clear sky value of 28.6 MJ m^{-2} day^{-1} for this latitude and time of year. However, on day 119, strong, dry, adiabatic southwesterly winds (mean 5 m s^{-1}, mean dew point 4.1°C, mean 2 m air temperature 20.1°C) caused H to be strongly positive, providing the extra energy needed to drive total LE to −32.8 MJ m^{-2} day^{-1}, even
FIGURE 6.5 Daily totals of energy balance terms for a fallow field (mostly bare Pullman clay loam) at Bushland, Texas. Note some missing R_n and H data in late summer.
FIGURE 6.6 Daily totals of energy balance terms for irrigated alfalfa at Bushland, Texas.

though both R_{si} and R_n levels were reduced in the afternoon due to cloudiness. Total LE was much larger in absolute magnitude than R_{si} and R_n totals. The next day, the total LE was 39% smaller due to the absence of regional advection, even though total R_{si} and R_n values were slightly larger. Values of G were near zero during this period of full canopy cover when leaf area index (LAI) was 7 (LAI is defined as the single-sided surface area of leaves per unit land area). Note that net radiation was negative at night. This is indicative of strong radiational cooling of the surface, which radiates heat into the clear, low-humidity nighttime skies common to this semiarid location at 1170 m above mean sea level.

Over alfalfa in late summer, R_{si} totals were lower (20.1 and 5.4 MJ m^{-2} day^{-1}, respectively, for days 254 and 255, 1997, Figure 6.3). On the very clear day 254, peak R_{si} was 798 W m^{-2}; and with regional advection occurring, LE flux was large. The 3 h period of negative H just after sunrise was due to the sun-warmed crop canopy being at greater temperature than the air. The arrival of a cool front bringing cloudy skies near midnight caused all fluxes to be much less on day 255, with R_{si} reaching only 220 W m^{-2}, and H near zero for much of the day. The arrival of the cloud

cover and moist air was signaled near midnight by the abrupt change from negative values of R_n and LE to near zero values. In the case of net radiation, this was due to the increased longwave radiation from the clouds, which were warmer and had larger emissivity than the clear sky that preceded them. Also near midnight, latent heat flux neared zero because the strong vapor pressure gradient from moist crop and soil to dry air was reduced by the arrival of moist air. Note that after sunset, but before midnight, latent heat flux was strong, due to continuing strong sensible heat flux, even though net radiation was negative. Again, due to full crop cover (LAI = 3), G values were small, indicating that very little energy was penetrating the soil surface.

For bare soil, G is often larger, becoming an important part of the energy balance (Figure 6.4). After rain and irrigation totaling 35 mm over the previous 2 days, the bare soil was wet on day 193, 1992, at Bushland, Texas. Latent heat flux totaled −14.4 MJ m^{-2} or 6 mm of evaporation; 77% of R_n. Sensible heat flux was negative for the first few hours after sunrise because the soil was warmer than the air, which had been cooled by a nighttime thunderstorm. Later in the day, H and G both approached zero, and near sunset, they became positive, supplying the energy consumed in evaporation that continued well into the night hours. Strong radiational cooling occurred on the nights of days 193 and 194 as indicated by negative values of R_n. Evaporation was probably energy limited on day 193, becoming soil limited on day 194. Latent heat flux on the second day was reduced to −7.4 MJ m^{-2}, and peak daytime values were not much larger in magnitude than those for G. The drying soil became warmer and contributed sensible heat to the atmosphere during almost all daylight hours.

Seasonal variations in daily total energy flux values occur due to changes of sun angle and day length, of distance from the earth to sun (about 3% yearly variation), of seasonal weather, and of surface albedo as plant and residue cover changes (Figures 6.5 and 6.6). A curve describing clear sky solar radiation at Bushland, Texas, would match the high points of R_{si} in Figures 6.5 and 6.6 well. Net radiation was similar for alfalfa and bare soil except for a rainy period beginning about day 190 when the soil was wet and dark and R_n for the fallow field was markedly larger. The big differences were in LE and H. Latent heat flux from the alfalfa was large, reaching nearly −40 MJ m^{-2} (16 mm) on day 136 during a regional advection event that allowed LE to be larger than R_{si}. Sensible heat flux was positive during much of the year. Soil heat flux was small during the growing season, becoming larger as the soil cooled during the fall and winter. For the bare soil, LE values were small during the first 150 days, the latter end of a drought (Figure 6.5). Sensible heat flux was negative during this period and remained negative after rains began until day 203. Evaporative fluxes were fairly small, rarely reaching 6 mm day^{-1} even after rains began. In contrast to alfalfa, soil heat flux for bare soil was larger and more variable throughout the year.

Methods of measurement and estimation of the energy fluxes are needed to characterize the energy balance. Examples of the instrumentation needed to measure components and subcomponents of the energy balance are given in Table 6.1. These will be discussed in the following sections.

TABLE 6.1   Example of Instruments and Deployment Information for Bare Soil Radiation
and Energy Balance Experiments at Bushland, Texas, 1992

Parameter	Instrument	Manufacturer[a] (Model)	Elevation	Description
R_{si}	Pyranometer	Eppley (PSP)[b]	1 m	Solar irradiance
αR_{si}	Pyranometer	Eppley (8–48)	1 m (I[c])	Reflected solar irradiance
$L\downarrow$	Pyrgeometer	Eppley (PIR)	1 m	Incoming longwave radiation
$L\uparrow$	Pyrgeometer	Eppley (PIR)	1 m (I)	Outgoing longwave radiation
R_n	Net radiometer	REBS (Q*6)	1 m	Net radiation
T_s	IR thermometer	Everest (4000; 60° fov)	1 m nadir view angle	Soil surface temperature
T_a	Thermistor	Rotronics		Air temperature and relative humidity
RH	Foil capacitor	(HT225R)	2 m	
U_2	DC generator cups	R.M. Young (12102)	2 m	Wind speed
U_d	Potentiometer vane	R.M. Young (12302)	2 m	Wind direction
T_t	Cu–Co thermocouple	Omega (304SS)	−10 mm and −40 mm	Soil temperature (4)[d]
G_{50}	Plates thermopile	REBS (TH-1)	−50 mm	Soil heat flux (4)
$\theta_{v\text{-}20}$	3-wire	Dynamax	−20 and −40 mm	Soil water content (2)
$\theta_{v\text{-}40}$	TDR probe	TR-100/20 cm	horizontal	
E_m	Lever-scale load cell	Interface (SM-50)	Below lysimeter box	Lysimeter mass change

6.2.1 Net Radiation

Net radiation is the sum of incoming and outgoing radiation

$$R_n = R_{si}(1-\alpha) - L\uparrow + L\downarrow, \tag{6.2}$$

where

R_{si} is solar irradiance at the surface (W m^{-2})
α is the albedo or surface reflectance (0–1)
$L\uparrow$ is the longwave radiance of the earth's surface (W m^{-2})
$L\downarrow$ is longwave irradiance from the sky (W m^{-2})

The sun radiates energy like a black body at about 6000 K, while the earth radiates at about 285 K. The theoretical maximum emission power spectra for these two bodies overlap very little (Figure 6.7), a fact that leads to description of radiation from the earth (including clouds and the atmosphere) as longwave, and radiation from the sun as shortwave. Note that the radiance of the earth is about 4 million times less than that of the sun (Figure 6.7). Net radiation may be measured by a net radiometer (Figure 6.8) or its components may be measured separately using pyranometers to measure incoming and reflected shortwave radiation, and pyrgeometers to measure incoming and outgoing longwave radiation (first four instruments
FIGURE 6.7   Emission power spectra for ideal black bodies at 6000 K (left, shortwave range) and 285 K (right, longwave range). Note that the units of the left-hand ordinate are 10^6 larger than those of the right-hand ordinate.

in Table 6.1). Pyranometers and pyrgeometers are thermopile devices that are sensitive equally across the spectrum. While net radiometers are usually much less expensive than four-component suites of pyrgeometers and pyranometers, there have

FIGURE 6.8   REBS Q*7 net radiometer.

FIGURE 6.9   Kipp & Zonen model CM-14 albedometer.

been consistent problems with calibration within a model series and biases between models from different companies leading to inconsistencies of up to 20% (Halldin, S., and A. Lindroth. 1992. Errors in net radiometry: Comparison and evaluation of six radiometer designs. J. Atmos. Ocean. Tech. 9:762–783; Kustas, W.P., J.H. Prueger, L.E. Hipps, J.L. Hatfield, and D. Meek. 1998. Inconsistencies in net radiation estimates from use of several models of instruments in a desert environment. Agr. Forest Meteorol. 90:257–263). Since no international standard exists for longwave radiation measurement and calibration, users are left with the options of cross-calibration of multiple instruments and comparisons with four-component pyrgeometer and pyranometer measurements. Continuing problems with net radiation measurement have made estimation of R_n from R_{si} a common practice that is discussed in Section 6.2.1.6.

6.2.1.1 Outgoing Longwave Radiation

The longwave radiance of the earth's surface, $L\uparrow$, is given by the Stefan–Boltzmann law for radiance from a surface at temperature T (K) and with emissivity ε (0–1).

$$L\uparrow = \varepsilon\sigma T^4, \tag{6.3}$$

where σ is the Stefan–Boltzmann constant (5.67×10^{-8} W m^{-2} K^{-4}). An inverted pyrgeometer (Table 6.1) may be used to measure $L\uparrow$ and, if accompanied by suitable surface temperature measurements, may allow estimation of surface emissivity, ε, by inversion of Equation 6.3. Surface temperature is often measured by suitably placed and shielded thermocouples, or remotely by infrared thermometer (IRT). There are problems with either type of measurement (radiational heating of the thermocouples, and uncertainty of the emissivity needed for accurate IRT measurements).

Values of α and ε for soil and plant surfaces may be estimated from published values relating them to surface properties (see Section 6.2.1.3 and Table 6.4). For soil, the dependence of α on water content is strong, but nearly linear, and amenable to estimation.

6.2.1.2 Solar Irradiance

Solar irradiance, R_{si}, includes both direct beam and diffuse shortwave radiation reaching the earth's surface and is defined

as the radiant energy reaching a horizontal plane at the earth's surface. It may be easily measured by pyranometer with calibration to international standards (Table 6.1) or by solar cells. Silicon photodetector solar radiation sensors such as the LI-COR model LI-200SA are sensitive in only part of the spectrum but are calibrated to give accurate readings in most outdoor light conditions. Silicon sensors are much cheaper than thermopile pyranometers and have found widespread use in field weather stations. Measurement of both incident (R_{si}) and reflected (R_{sr}) shortwave allows estimation of the albedo from

$$R_{si}(1 - \alpha) = R_{si} - R_{sr}. \tag{6.4}$$

This is done using upward and downward facing matched pyranometers (Table 6.1). Specially made albedometers are available for this purpose (e.g., Kipp & Zonen model CM-14; Figure 6.9).

In the absence of measurements, solar irradiance may be estimated from the sun's brightness above the atmosphere R_a (W m^{-2}) and reductions in surface irradiation mediated by latitude, time of day and year, and elevation. Such estimates also provide a useful check on measurements by providing an upper bound to R_{si}, the clear sky solar irradiance, R_{so}. The "solar constant" is the flux density of solar radiation on a plane surface perpendicular to the direction of radiation and outside the earth's atmosphere. It is 1366 W m^{-2} on average, with a within-year variation of about ±3.5%, being largest in January when the sun is closest to the earth and smallest in July (Jones, 1992). Several satellite observation platforms have recorded the value of solar irradiance, R_a, over a >20 year span (Figure 6.10) and clearly show the average solar cycle of 11 years (Fröhlich and Lean, 1998). The data range over about 0.36% of the mean value when corrected for earth–sun distance. Thus, considering the "solar constant" to be 1366 W m^{-2} will introduce a <1% error in calculations when corrected for earth–sun distance.

Irradiance at the earth's surface is somewhat less, due to absorption and scattering in the atmosphere and due to sun angle effects, not often exceeding 1000 W m^{-2}. The further the sun is from the zenith the longer the transmission path through the atmosphere, and the more absorption and scattering occurs. Also, as sun angle above the horizon, β (radians), decreases (it is
FIGURE 6.10 Composite of observations of total solar irradiance (R_a) outside the earth's atmosphere from six satellites: NIMBUS-7, SMM, ERBS, UARS, SOHO, and ACRIM-Sat (corrected for earth–sun distance). (ftp://ftp.ngdc.noaa.gov/STP/SOLAR_DATA/SOLAR_IRRADIANCE/composite_d25_07_0310a.dat. Graph constructed using version d25_07_0310a of the dataset from PMOD/WRC, Davos, Switzerland, including unpublished data from the VIRGO experiment on the cooperative ESA/NASA Mission SoHO; Fröhlich, C., and J. Lean. 1998. The sun's total irradiance: Cycles, trends and related climate change uncertainties since 1976. Geophys. Res. Lett. 25:4377–4380.)

greatest at solar noon) the radiation density, I, on a horizontal surface decreases according to Lambert's law

$$I = I_o \sin(\beta), \tag{6.5}$$

where I_o is the flux density on a surface normal to the beam.

Sun angle (β) changes with time of day and year, and can be calculated from

$$\beta = \sin^{-1}[\sin(\delta)\sin(\phi) + \cos(\delta)\cos(\phi)\cos(t_{sa})], \tag{6.6}$$

where

ϕ is latitude
δ is solar declination
t_{sa} is solar time angle (all radians)

Solar time angle is defined as

$$t_{sa} = \frac{(t - t_{SN})2\pi}{24}, \tag{6.7}$$

where

t is time (h)
t_{SN} is the time (h) of solar noon

The time of solar noon varies with time of year and longitude according to (recall that 1° longitude = 4 min):

$$t_{SN} = 12 + \frac{4(\text{longitude} - \text{local meridian})}{60} - t_{EQ}, \tag{6.8}$$

where

t_{EQ} is the "equation of time" value (h)
longitude is in degrees
the local meridian is the longitude (°) for which standard time is calculated for the time zone in question

In the United States, the meridians for Eastern Standard Time (EST), Central Standard Time (CST), Mountain Standard Time (MST), and Pacific Standard Time (PST) are 75°, 90°, 105°, and 120°, respectively. Local or true solar time (t_{LS}, h) for any local standard time (t_{ST}) may be calculated with

$$t_{LS} = t_{ST} - 4\frac{(\text{longitude} - \text{local meridian})}{60} + t_{EQ}. \tag{6.9}$$

The declination (radians) may be calculated from (Rosenberg et al., 1983)

$$\delta = 0.4101\cos\left[\frac{2\pi(J - 172)}{365}\right], \tag{6.10}$$

where J is the day of the year.

List (1971) gave "equation of time" values to the nearest second for the first of each month and every 4 days after that for each month (95 values for the year). The following equation reproduces those values with a maximum error of 6 s and can be used to estimate t_{EQ} (h) for any day of the year.

$$t_{EQ} = b_0 + b_1\sin\left(\frac{J}{P_1}\right) + b_2\cos\left(\frac{J}{P_1}\right) + c_1\sin\left(\frac{J}{P_4}\right) + c_2\cos\left(\frac{J}{P_4}\right)$$
$$+ c_3\sin\left(\frac{2J}{P_4}\right) c_4\cos\left(\frac{2J}{P_4}\right) + c_5\sin\left(\frac{3J}{P_4}\right) + c_6\cos\left(\frac{3J}{P_4}\right)$$
$$+ c_7\sin\left(\frac{4J}{P_4}\right) + c_8\cos\left(\frac{4J}{P_4}\right), \tag{6.11}$$

where the coefficients b_1 and c_1 are given in Table 6.2, and $P_1 = 182.5/(2\pi)$ and $P_4 = 365/(2\pi)$.

Jensen et al. (1990) gave a simpler method for t_{EQ}:

$$t_{EQ} = 0.1645\sin(2b) - 0.1255\cos(b) - 0.025\sin(b), \tag{6.12}$$

where $b = 2\pi(J - 81)/364$. The maximum error compared against List's t_{EQ} values is 88 s.

Disregarding air quality, solar irradiance is affected by latitude, time of year and day, and elevation. Latitude and time affect the sun angle, β, and so affect both the path length of radiation through the atmosphere (and thus absorption and scattering losses) and the flux density at the surface through Equation 6.5. Elevation affects the path length. Methods for calculating extraterrestrial, R_{sa}, and clear sky solar irradiance at the surface, R_{so}, are given by ASCE (2005), Campbell (1977, Chapter 5),

TABLE 6.2 Coefficients for Calculating the "Equation of Time" Value from Equation 6.11

b_0	4.744×10^{-5}	c_2	9.19×10^{-3}	c_6	-1.29×10^{-3}
b_1	-0.157	c_3	-5.78×10^{-4}	c_7	-3.23×10^{-3}
b_2	-0.0508	c_4	3.61×10^{-4}	c_8	-2.1×10^{-3}
c_1	-0.122	c_5	-5.48×10^{-3}		

Jensen et al. (1990, Appendix B), Jones (1992, Appendix 7), and McCullough and Porter (1971). Calculation of R_{sa} depends on latitude and time of day. Once R_{sa} is calculated, R_{so} may be estimated from considerations of absorption and scattering in the atmosphere, which depend mainly on the path length through the atmosphere and its density. Thus latitude, time of day, and elevation are factors in estimating R_{so} from R_{sa}. The value of R_{so} is an important quantity against which to check measured R_{si}; and it can be used in estimates of R_n, either to replace R_{si} in Equation 6.2 or to use location-specific regression relationships of $R_n = f(R_{so})$ (see Jensen et al., 1990, Appendix B). Duffie and Beckman (1991) presented the following method of calculating R_{sa} (MJ m^{-2} h^{-1}) for any period, τ (h),

$$R_{sa} = \left[\frac{24(60)}{2\pi}\right] G_{SC} d_r \{\cos(\phi)\cos(\delta)[\sin(\omega_2) - \sin(\omega_1)]$$
$$+ (\omega_1 - \omega_2)\sin(\phi)\sin(\delta)\}, \qquad (6.13)$$

where

    G_{SC} is the solar constant (0.08202 MJ m^{-2} min^{-1})
    d_r is the relative earth–sun distance
    ω_1 and ω_2 are the solar time angles at the beginning and end of the period, respectively (all angles in radians)

The term $24(60)/(2\pi)$ is the inverse angle of rotation per minute. The relative earth–sun distance, d_r, is given by

$$d_r = 1 + 0.033\cos\left(\frac{2\pi J}{365}\right), \qquad (6.14)$$

where J is the day of year. The solar time angles at the beginning and end of the period in question are given by

$$\omega_1 = \omega - \frac{\pi}{(24/\tau)}, \qquad (6.15)$$

$$\omega_2 = \omega + \frac{\pi}{(24/\tau)}, \qquad (6.16)$$

where

    ω is the solar time angle at the center of the period (radians)
    τ is the length of the period in hours

Calculation of R_{sa} for an entire day requires knowledge of the sunrise and sunset times. The sunset time angle (angle from solar noon to sunset, radians) is given by

$$\omega_s = \cos^{-1}[-\tan(\phi)\tan(\delta)], \qquad (6.17)$$

from which it is clear that day length, t_D (h), is

$$t_D = \frac{24\omega_s}{\pi}. \qquad (6.18)$$

Equation 6.13 can be rewritten for total daily R_{sa} as

$$R_{sa} = \left[\frac{24(60)}{\pi}\right] G_{SC} d_r [\cos(\phi)\cos(\delta)\sin(\omega_s) + \omega_s \sin(\phi)\sin(\delta)]. \qquad (6.19)$$

For example, on day 119 at latitude 35°11′N, longitude 102°6′W, R_{sa} calculated using Equation 6.13 on a half-hourly basis totaled 38.097 MJ m^{-2} compared with 38.100 MJ m^{-2} calculated with Equation 6.19.

Jensen et al. (1990) recommended estimating daily total clear sky solar irradiance as

$$R_{so} = 0.75 R_{sa} \qquad (6.20)$$

Somewhat in agreement with this, Monteith and Unsworth (1990) stated that direct beam radiation rarely exceeded 1030 W m^{-2}, about 75% of the solar constant.

Jones (1992) and Monteith and Unsworth (1990) suggested

$$R_{si} = R_{si\_max} \sin\left(\frac{\pi t}{N}\right), \qquad (6.21)$$

for instantaneous values of R_{si} on clear days, where R_{si_max} is the maximum instantaneous irradiance occurring at solar noon, t is time after sunrise (h), and N is day length (h).

Rather than R_{si_max}, it is more common to know daily total R_{si}. Collares-Pereira and Rabl (1979) gave the ratio of hourly irradiance, $R_{si,h}$ to daily irradiance, $R_{si,d}$ as

$$\frac{R_{si,h}}{R_{si,d}} = \left(\frac{\pi}{24}\right)(a + b\cos\omega)\frac{(\cos\omega - \cos\omega_S)}{(\sin\omega_S - \omega_S \cos\omega_S)}, \qquad (6.22a)$$

where

$$a = 0.409 + 0.5016\sin\left(\omega_S - \frac{\pi}{3}\right) \qquad (6.22b)$$

and

$$b = 0.6609 + 0.4767\sin\left(\omega_S - \frac{\pi}{3}\right) \qquad (6.22c)$$

Equation 6.22 performed well when applied to data from Bushland, Texas (Figure 6.11).

More complex methods of estimating R_{so} account for attenuation of direct beam radiation using Beer's law, coupled with Lambert's law to calculate irradiance on a horizontal surface, plus an accounting of diffuse irradiance (see, e.g., List, 1971; Rosenberg et al., 1983; Jones, 1992). Beer's law describes the intensity I of radiation after passing a distance x through
FIGURE 6.11 Solar irradiance measured at Bushland, Texas, in 1992 and 1997 on clear and cloudy days (open circles) and Equation 6.22a half-hourly predictions (lines).

a medium in terms of an extinction coefficient, k, and the initial intensity, I_a, as

$$I = I_a e^{kx}. \tag{6.23}$$

For solar radiation, the distance is expressed in terms of air mass number, m, as (List, 1971)

$$m = \sec\left(\frac{\pi}{2} - \beta\right). \tag{6.24}$$

The air mass is referenced to the length of the path when the sun is directly overhead. For β less than 0.175 radians (10°), the

measured air mass number is less than that given by Equation 6.24 due to refraction and reflection at these low angles. List (1971) gives corrections and notes also that for pressures, p, less than standard sea-level pressure, p_0, that m should be corrected by $m = m(p/p_0)$. Rewriting Equation 6.23, we have

$$I_o = I_a e^{k \sec(\pi/2 - \beta)}, \tag{6.25}$$

where I_o is direct beam radiation at the earth's surface. Monteith and Unsworth (1990) give a range of values of k for England as 0.07 for very clean air and 0.6 for very polluted air.

Assuming that both direct, I_o, and diffuse, I_d, radiation are known, the total irradiance at the surface is

$$R_{si} = I_o(\sin\beta) + I_d. \tag{6.26}$$

Diffuse radiation is difficult to estimate because it is so dependent on cloud cover and aerosol concentration in the air. Yet, summarizing several data sets, Spitters et al. (1986) found that the proportion of R_d to R_{si} is a function of the ratio of R_{si} to R_{sa} (Figure 6.12) described for daily total R_{si} by

$$R_{d,d} = 1, \quad \frac{R_{si,d}}{R_{sa,d}} < 0.07 \tag{6.27a}$$

$$\frac{R_{d,d}}{R_{si,d}} = 1 - 2.3\left(\frac{R_{si,d}}{R_{sa,d}} - 0.07\right)^2, \quad 0.07 \le \frac{R_{si,d}}{R_{sa,d}} < 0.35 \tag{6.27b}$$

$$\frac{R_{d,d}}{R_{si,d}} = 1.33 - 1.46\left(\frac{R_{si,d}}{R_{sa,d}}\right), \quad 0.35 \le \frac{R_{si,d}}{R_{sa,d}} < 0.75 \tag{6.27c}$$

$$\frac{R_{d,d}}{R_{si,d}} = 0.23\left(\frac{R_{si,d}}{R_{sa,d}}\right), \quad 0.75 \le \frac{R_{si,d}}{R_{sa,d}}, \tag{6.27d}$$
FIGURE 6.12 Daily (a) and hourly (b) relationships between R_d/R_{si} and R_{si}/R_{sa}. (Reprinted from Spitters, C.J.T., H.A.J.M. Toussaint, and J. Goudriaan. 1986. Separating the diffuse and direct component of global radiation and its implications for modeling canopy photosynthesis. Part I. Components of incoming radiation. Agr. Forest Meteorol. 38:217–229.)

and for hourly values by

$$R_{d,h} = 1, \quad \frac{R_{si,h}}{R_{sa,h}} \le 0.22 \qquad (6.28a)$$

$$\frac{R_{d,h}}{R_{si,h}} = 1 - 6.4\left(\frac{R_{si,h}}{R_{sa,h}} - 0.22\right)^2, \quad 0.22 < \frac{R_{si,h}}{R_{sa,h}} \le 0.35 \qquad (6.28b)$$

$$\frac{R_{d,h}}{R_{si,h}} = 1.47 - 1.66\left(\frac{R_{si,h}}{R_{sa,h}}\right), \quad 0.35 < \frac{R_{si,h}}{R_{sa,h}} \le K \qquad (6.28c)$$

$$\frac{R_{d,h}}{R_{si,h}} = R, \quad K < \frac{R_{si,h}}{R_{sa,h}}, \qquad (6.28d)$$

where

$$R = 0.847 - 1.61\sin\beta + 1.04\sin^2\beta \qquad (6.29)$$

and

$$K = \frac{(1.47 - R)}{1.66} \qquad (6.30)$$

6.2.1.3 Surface Albedo and Emissivity

Because R_{si} provides most of the energy that is partitioned at the earth's surface, albedo plays a major role in the energy balance. The mean albedo of the earth is 0.36 ± 0.06 (Weast, 1982). But albedo varies diurnally (Figure 6.13) with larger albedo corresponding to lesser sun angle (see also bare soil data of Monteith and Szeicz, 1961; Idso et al., 1974; Aase and Idso, 1975). Soil and plant

surfaces are often considered optically rough, but in some cases, specular (mirror-like) rather than diffuse reflection may occur. Some plant leaves are shiny and reflect specularly when the angle of incident radiation is small. Wet soil surfaces may also reflect specularly. These mechanisms lead to larger albedo when sun angle is smaller. The albedo of plant stands is also smaller in midday because more sunlight penetrates deeply within the canopy and is trapped by multiple reflections. Wilting and other physiological changes during the day may also contribute to changes in albedo.

Soil albedo decreases as water content increases. Bowers and Hanks (1965) found the relationship to be curvilinear, as did Skidmore et al. (1975). Working with thinner soil layers, Idso and Reginato (1974) found that bare soil albedo changed linearly with water content of the surface 2 mm of soil (smooth clay loam; Figure 6.14). For thicker layers, the relationship was curvilinear. The maximum albedo, 0.3, occurred for air dry soil, but the minimum albedo, 0.14, occurred at about $0.23\,\text{m}^3\,\text{m}^{-3}$ water content, much less than saturation. This represents field capacity (soil water tension of 30 kPa) for this soil; and Idso and Reginato (1974) postulated that the minimum albedo would occur at field capacity for all soils. Kondo et al. (1992) found a similar relationship for a bare loam with a maximum albedo of 0.24 and minimum of 0.13, and with the minimum attained when soil water content reached about $0.22\,\text{m}^3\,\text{m}^{-3}$. Data of Idso et al. (1974, 1975) show that the difference between wet and dry soil albedos was constant despite the diurnal variation of albedo or the day of year. Similarly, Monteith (1961) measured albedo of clay loam to be 0.18 when dry, decreasing to 0.11 when at field capacity water content of $0.35\,\text{m}^3\,\text{m}^{-3}$.

The interaction of sun angle and soil drying causes complex patterns of soil albedo change over time. Figure 6.13 illustrates low daytime wet soil albedos of 0.11 after irrigation and rain on days 191 and 192, 1992, at Bushland, Texas. Rapid soil surface drying on day 193 caused albedo to rise sharply during the day. Additional drying on day 194 completed the change, and
FIGURE 6.13 Albedo plotted as a function of time for smooth, bare Pullman clay loam at Bushland, Texas, in the daytime, when wet, during drying, and dry.
FIGURE 6.14 Albedo, normalized according to sun angle, versus soil water content for different surface layer thicknesses of Avondale clay loam at Phoenix, AZ. Solid circles describe albedo versus water content at the surface. Data for shaded areas are uncertain. (From Idso, S.B., and R.J. Reginato. 1974. Assessing soil-water status via albedo measurement. Hydrol. Water Resour. Arizona SW 4:41–54.)

diurnal albedo changes on days 195 and 196 reflected only sun angle effects, with a minimum albedo of 0.2 for this smooth soil surface. The same surface in a roughened condition earlier in the year never reached midday albedo values larger than 0.13.

Other than water content, major determinants of soil albedo are color, texture, organic matter content, and surface roughness. Dvoracek and Hannabas (1990) presented a model of albedo dependence on sun angle, surface roughness, and color

$$\alpha = p^{(c \sin \beta + 1)}, \tag{6.31}$$

where
   p is a color coefficient
   c is a roughness coefficient
   β is solar angle

They demonstrated good fits with measured data (Table 6.3). Albedo values modeled using p and c values from Table 6.3 for wheat and cotton (day of year 192, latitude 41°N) appear realistic (Figure 6.15). However, the physical meaning of the p and c coefficients is not well understood.

Daily mean albedos may be calculated as the ratio of daily total reflected shortwave energy to daily total R_{si}. Using data from Figures 6.5 and 6.6, daily mean albedos for fallow (soybean residue) and alfalfa differ by about 0.10 when the soil is very dry (Figure 6.16). The gradual decline in fallow albedo in early 1996 may be due to decomposition of the soybean residue.

TABLE 6.3 Color (p) and Roughness (c) Coefficients for Equation 6.31

Surface and Condition	Color Coefficient p	Roughness Coefficient c	Mean r^2
Lakes and ponds, clear water			
Waves, none	0.13	0.29	0.82
Waves, ripples up to 2.5 cm	0.16	0.70	0.74
Waves, larger than 2.5 cm with occasional whitecaps	0.23	1.25	0.83
Waves, frequent whitecaps	0.30	2.00	0.85
Lakes and ponds			
Green water, ripples up to 2.5 cm	0.22	0.70	0.90

FIGURE 6.15 Albedo for wheat and cotton versus sun angle and wind speed (u) according to Equation 6.31.
FIGURE 6.16 Daily mean albedos for irrigated alfalfa and fallow after soybean on Pullman clay loam at Bushland, Texas.

Albedo for the alfalfa field declined at each cutting to nearly that of the fallow field, which was initially rougher than the soil under the alfalfa. But, during heavy rains in the latter part of the year, the fallow soil surface was slaked and smoothed and its albedo increased to near that of the alfalfa. Thus, after the fourth cut, the alfalfa field albedo was lower than that of the fallow field for a brief time, probably because the alfalfa was irrigated and the fallow field had dried out again. Peaks of albedo exceeding 0.8 were due to snow early and late in the year. In contrast to soil, albedo of closed canopies (well watered) is relatively constant (Table 6.4).

Albedo values for many plant covers may be found in Gates (1980). For surfaces with plants, the amount of radiation reaching the soil surface, R_t (Figure 6.1), depends on the LAI and the canopy structure. Numerical models have been developed that take into account leaf orientation and distribution in the canopy to calculate absorption of radiation at different levels in the canopy (Goudriaan, 1977; Chen, 1984). Lascano et al. (1987) used Chen's model to calculate polynomials representing the dependence of albedo on LAI, as well as the dependence of the

view factor (proportion of sky visible from the soil) on LAI, and incorporated these into their ENergy and WATer BALance model (ENWATBAL). Monteith and Unsworth (1990) presented equations describing the albedo of a deep canopy with a spherical distribution of leaves for sun angles greater than 25°. More discussion of these concepts can be found in Russell et al. (1989). For field studies we can either measure albedo, directly measure the components of net radiation, or use a net radiometer (Table 6.1).

Because of the largely unpredictable and time-varying position of sun flecks below the canopy, transmitted radiation can be measured below the canopy most effectively with one of the linear radiation sensors rather than with point sensors. Linear sensors are typically 1 m long and integrate radiation over their entire length. Some are equipped with diffusers. The tube solarimeter is enclosed in a clear envelope and accepts radiation from all directions. Some other linear sensors are configured to accept only down welling radiation; for example, transmitted photosynthetically active radiation (400–700 nm) can be measured below the canopy with a "line quantum sensor" (LI-Cor, Lincoln, Nebraska, USA) or with a "crop canopy absorption meter" (ICT International, Armidale, New South Wales, Australia). For either, the results may be usefully related to total shortwave irradiance through a linear regression, or the latter sensor may be ordered with sensitivity across the shortwave spectrum from 400 to 950 nm.

6.2.1.4 Spectral Reflection and Radiation

The discussion of emissivities and albedos of surfaces given here is based on a broadband view of irradiance, reflection, and emission that recognizes only shortwave and longwave radiation as presented in Figure 6.7. Although these are arguably the most important features from an energy balance perspective, there is much recent work on multispectral sensing of radiation reflected and emitted from vegetation and soil surfaces (Van Toai et al., 2003). This spectral sensing may be done for only a few relatively narrow bands of radiation in the visible and infrared (IR), or may involve hyperspectral scanning that provides sensing of radiation for every nanometer of the spectrum across a wide range. The advent of fiber optics capable of transmitting both visible and IR light and the development of miniaturized spectrometers (e.g., Ocean Optics, Inc., model S2000) has revolutionized the way researchers view plant and soil surfaces.

An example of multispectral sensing is the use of red and near infrared (NIR) reflectance from a cotton canopy (Figure 6.17). The ratio of NIR/red reflectances is clearly related to LAI. However, the relationship is not stable from year to year and research continues. Other uses include sensing of the onset and progression of plant disease and insect infestation, and sensing of plant water status. Much work remains to be done to make these techniques useful.

6.2.1.5 Incoming Longwave Radiation

Methods of estimating longwave irradiance from the sky, $L\downarrow$, usually take the form

$$L\downarrow = \varepsilon_a \sigma (T_a + 273.16)^4, \tag{6.32}$$

where T_a (°C) is air temperature at the reference measurement level (often 2 m), and the emissivity (ε_a) may be estimated from the vapor pressure of water in air at reference level (e_a) (kPa) or from both e_a and T_a.

The vapor pressure is

$$e_a = \frac{RH}{100} e_s, \tag{6.33}$$
FIGURE 6.17 Reflectance factor versus wavelength for bare soil and cotton at three levels of LAI (a), and the relationship between the ratio of NIR to red reflectance and LAI (b) for cotton in Arizona. (Personal communication from P.J. Pinter Jr. and E.M. Barnes, U.S. Water Conservation Laboratory, USDA-ARS, Phoenix, AZ, May 2000.)

where

RH is the relative humidity of the air

e_s is the saturation vapor pressure (kPa) at T_a (°C) given by (Murray, 1967)

$$e_s = 0.61078 \exp\left(\frac{17.269 T_a}{237.3 + T_a} \right). \tag{6.34}$$

If the dew point temperature, rather than the RH, is known then

$$e_a = 0.61078 \exp\left(\frac{17.269 T_{dew}}{237.3 + T_{dew}} \right). \tag{6.35}$$

Hatfield et al. (1983) compared several methods for estimating ε and concluded that methods using only air temperature performed less well than those that used vapor pressure or both vapor pressure and air temperature. Among the best methods was Idso's (1981) equation

$$\varepsilon_a = 0.70 + 5.95 \times 10^{-4} e_a \exp\left[\frac{1500}{T_a + 273.1} \right], \tag{6.36}$$

where e_a is in kPa. Idso showed fairly conclusively that ε is a function of both e_a and T_a.

Howell et al. (1993) measured $L\downarrow$ (Table 6.1) and calculated ε_a by inverting Equation 6.32. Applying Equation 6.36 as well as Brunt's (1932) equation

$$\varepsilon_a = 0.52 + 0.206 e_a^{0.5} \tag{6.37}$$

and Brutsaert's (1982) equation

$$\varepsilon_a = 0.767 e_a^{1/7} \tag{6.38}$$

to their data shows that all three equations gave good predictions for clear sky conditions but probably underestimated ε_a for cloudy and nighttime conditions (Figure 6.18). For regressions of predicted versus measured ε, the Idso equation gave a slightly greater correlation coefficient and a slope closer to unity (Table 6.5). Under heavy clouds, sky emissivity approaches unity; and none of these models predicts this well.

Choi et al. (2008) found similar results in a humid climate (Florida), where the Brunt and Brutsaert models both performed well under clear sky conditions, but $L\downarrow$ was underestimated under cloudy conditions. They compared seven methods of estimating down welling longwave radiation under clouds, $L\downarrow_c$, and found that the Crawford and Duchon (1999) model $(L\downarrow_c = L\downarrow (1 - c_c) + c_c \sigma T_a^4)$ worked best where c_c was fractional cloud cover.
FIGURE 6.18 Comparison of predictions with measured emissivity for two periods in 1992 at Bushland, Texas. Points plotted at extreme right were associated with nighttime and overcast conditions. A, Equation 6.37; B, Equation 6.38; C, Equation 6.36. Lines are for regressions shown in Table 6.5.

Method	Regression Equation	r^2	SE
Brunt, Equation 6.37	$\varepsilon_p = 0.505 + 0.325\varepsilon$	0.33	0.024
Brutsaert, Equation 6.38	$\varepsilon_p = 0.556 + 0.311\varepsilon$	0.32	0.024
Idso, Equation 6.36	$\varepsilon_p = 0.522 + 0.398\varepsilon$	0.37	0.027

Despite the difficulty of estimating sky emissivity well, uncertainty in the value of $L\downarrow$ usually causes little difficulty in estimating net radiation for daytime; but $L\downarrow$ can be seriously underestimated at night with important consequences for models of chill stress or frost.

6.2.1.6 Comparison of Net Radiation Estimates with Measured Values

It has become commonplace to have data from field weather stations that include R_{si} (W m^{-2}), and air temperature, T_{az} (°C), wind speed, u_z (m s^{-1}), and relative humidity, RH$_z$ (%), measured at some reference height, z (often 2 m). Measurement of R_n is still not common, probably due to several factors including additional expense, fragility of the plastic domes used on some models of net radiometer, and problems with calibration, including wind speed effects. Net radiometer calibration changes with time; and experience shows that even new radiometers may not agree within 10%. If a net radiometer is used, it is prudent, as with all instruments, to check measured R_n values against estimated ones. Methods presented in previous sections can be used to estimate R_n, but simpler methods exist that are adequate for most cases. Jensen et al. (1990) compared four methods of estimating R_n, including those of Wright and Jensen (1972), Doorenbos and Pruitt (1977), a combination of Brutsaert (1975) and Weiss (1982), and Wright (1982),

against values measured at Copenhagen, Denmark, and Davis, California. The Wright (1982) method was overall best, but underestimated R_n in the peak month at Copenhagen by 9%. The Wright and Jensen (1972) method was almost as good. These methods all assume that surface temperature is not measured, so that only air temperature is used in the calculations.

Jensen et al. (1990) calculated net longwave radiation, R_{nl}, as

$$R_{nl} = -\left[a\left(\frac{R_{si}}{R_{so}}\right) + b\right](a_1 + b_1 e_d^{0.5})\sigma T_{az}^4, \quad (6.39)$$

where

e_d is the saturation vapor pressure of water in air at dew point temperature (kPa)

the term $(a_1 + b_1 e_d^{0.5})$ is a "net emittance," ε', of the surface

The "net emittance" attempts to compensate for the fact that surface temperature is not measured, the assumption being that T_{az} can substitute reasonably well for both sky and surface temperature. The coefficients a, b, a_1, and b_1 are climate specific, with a and b being cloudiness factors. Some values are presented by Jensen et al. (1990, Table 6.3.3).

Many weather stations report only daily totals of solar radiation; and maximum and minimum of air temperature, T_x and T_n, respectively (K). If this is the case, the term σT^4 can be estimated as

$$\sigma T^4 \cong \frac{\sigma(T_x^4 - T_n^4)}{2}. \quad (6.40)$$

If mean dew point temperature is not available, it may be estimated as equal to T_n in humid areas.

Allen et al. (1994a, 1994b) gave slightly modified versions of the methods presented by Jensen et al. (1990) in a proposed FAO standard for reference ET estimation. As an example, estimates of daily total net radiation were made for Bushland, Texas, using the following equations

$$R_n = (1-\alpha)R_s - \left[a_c\left(\frac{R_{si}}{R_{so}}\right) + b_c\right](a_1 + b_1 e_d^{0.5})\sigma\left(\frac{T_m^4 + T_n^4}{2}\right), \quad (6.41)$$

where the cloud factors were $a_c = 1.35$ and $b_c = -0.35$, the emissivity factors were $a_1 = 0.35$ and $b_1 = -0.14$, the albedo was $\alpha = 0.23$, R_{si} was measured, e_d was calculated from mean dew point temperature, and R_{so} was calculated from

$$R_{so} = (0.75 + 0.00002\,EL_{msl})R_{sa}, \quad (6.42)$$

where

R_{sa} is from Equation 6.19

EL_{msl} is elevation (m) above mean sea level

This is similar to Equation 6.20 but with a correction increasing R_{so} for higher elevation sites. The mean daily saturated vapor pressure at dew point temperature was estimated from mean daily dew point temperature, T_d (°C)

$$e_d = 0.611\exp\left[\frac{17.27T_d}{T_d + 237.3}\right]. \quad (6.43)$$

Additionally, half-hourly R_n estimates were calculated from half-hourly measured values of R_{si}, T_a, and T_d using equations given by Allen et al. (1994a, 1994b) equivalent to Equations 6.7, 6.8, 6.10, and 6.12 through 6.16 to estimate half-hourly R_{sa}, and Equation 6.42 to estimate half-hourly R_{so}. Equation 6.43 was applied to half-hourly dew point temperatures to estimate half-hourly e_d values. Equation 6.41 was written for half-hourly values of air temperature, T_a, as

$$R_n = (1-\alpha)R_s - \left[a_c\left(\frac{R_{si}}{R_{so}}\right) + b_c\right](a_1 + b_1 e_d^{0.5})\sigma(T_a^4), \quad (6.44)$$

where the ratio of R_{si} to R_{so} was set to 0.7 for nighttime estimates of R_n.

Comparison of daily R_n estimates, calculated using half-hourly data means, with measurements made with a Radiation and Energy Balance Systems (REBS) Q*5 (Seattle, Washington) net radiometer over irrigated grass show excellent agreement for alfalfa (Figure 6.19) and grass (Figure 6.20) at Bushland, Texas. But, there was a consistent bias for R_n estimated from daily means, with underestimation of R_n at large measured values,
FIGURE 6.19 Daily net radiation, estimated with methods from Allen, R.G., M. Smith, A. Perrier, and L.S. Pereira. 1994a. An update for the definition of reference evapotranspiration. ICID Bull. 43:1–34; Allen, R.G., M. Smith, A. Perrier, and L.S. Pereira. 1994b. An update for the calculation of reference evapotranspiration. ICID Bull. 43:35–92. Using half-hourly data, compared with measurements with a REBS Q*5 net radiometer over sprinkler irrigated alfalfa in 1996 at Bushland, Texas.
FIGURE 6.20 Net radiation estimated with methods from Allen et al. (1994a, 1994b) compared with measurements over drip irrigated grass in 1996 at Bushland, Texas.
FIGURE 6.21 Daily net radiation, estimated with methods of Allen et al. (1994a, 1994b) using daily means and maxima and minima, compared with measurements with a REBS Q*5 net radiometer over drip irrigated grass in 1996 at Bushland, Texas.

and overestimation at small measured values (Figure 6.21). The bias evident when daily means and maximum/minimum temperatures were used is probably tied to both poor estimates of vapor pressure from the max/min temperature data, and the inadequacy of Equation 6.40.

Estimates of half-hourly net radiation for alfalfa at Bushland, Texas, made using half-hourly data and these methods also gave good results (Figure 6.22). Allen et al. (1994a, 1994b) give detailed methods for estimating R_n when measurements are missing for R_{si} and/or e_d. Irmak et al. (2003) give useful methods for estimating R_n when only measured T_x, T_n, and R_{si} are available, or when only measured T_x, T_n, and RH are available and R_{si} is estimated.
FIGURE 6.22 Half-hourly measured net radiation compared with values estimated with methods of Allen et al. (1994a, 1994b) using half-hourly data for drip irrigated grass at Bushland, Texas, 1996.

6.2.2 Latent Heat Flux

Latent heat flux, LE (W m^{-2}), is the product of the evaporative flux, E (kg s^{-1} m^{-2}), and the latent heat of evaporation, λ (2.44 × 10^6 J kg^{-1} at 25°C). The value of λ is temperature dependent, but is well described (in J kg^{-1} × 10^6) by

$$\lambda = 2.501 - 2.370 \times 10^{-3} T \ \ (r^2 = 0.99995), \tag{6.45}$$

where T is in °C. Methods of E measurement include weighing lysimeters (including microlysimeters), and other mass balance techniques that rely on measurements of change in soil water storage, ΔS. Evaporative flux may also be estimated from other measurement methods such as eddy covariance (EC) and Bowen ratio measurements or from models ranging from the relatively simple analytical form of the Penman–Monteith (P–M) equation to complex field surface energy balance (FSEB) models. The surface renewal method is also a possibility (Snyder et al., 1997), but may be biased in some conditions (Zapata and Martinez-Cob, 2002) and depends on measurements above the crop and knowledge of the measurement height and crop height. Castellví (2004) addressed problems with surface renewal analysis by combining it with similarity theory. The surface renewal approach has so far not become widely used in agricultural micrometeorology and will not be further discussed herein. Because ΔS is a component of the soil water balance, and weighing lysimetry is a key tool for investigations of soil water balance, discussion of lysimetric techniques will be deferred to Section 6.3.

6.2.2.1 Boundary Layers

Evaporative fluxes move between plant or soil surfaces and the air by both diffusion and convection. Diffusive processes prevail in the laminar sublayer close (millimeters) to these surfaces. In this layer, air movement is parallel to the surface and little mixing occurs. Vapor flux across the laminar sublayer is well described by a Fickian diffusion law relating flux rate to vapor pressure gradient factored by a conductance term. But in the

turbulent layer beyond the laminar layer, the flux is mostly convective in nature so that water vapor is moved in parcels of air that are emitted and mixed into the atmosphere in turbulent flow. These moving parcels of air are often referred to as eddies and are analogous to eddies seen in a stream. Usually the eddies are not visible; but in foggy, smoky, or dusty conditions, they may be apparent. Certainly, anyone who has felt the buffeting of the wind can attest to the force of eddies and the turbulence of the airstream in which they occur. As wind speeds increase, the depth of the laminar sublayer decreases. Surface roughness enhances this process, resulting in thinner laminar sublayers. Because the resistance to vapor transport across the laminar airstream is much larger than the resistance across a turbulent airstream of similar dimension, increasing roughness and wind speed both tend to enhance vapor transport. If the air is still, then eddies due to turbulent flow do not exist, but eddies due to free convection may well be present. Free convection occurs when an air parcel is warmer (or colder) than the surrounding air and thus moves upward (or downward) because it is lighter (or heavier). These buoyancy effects can predominate at very low wind speeds when the surface is considerably warmer than the air. As opposed to free convection, transport in eddies due to wind is called forced convection. A full discussion of the fluid mechanics of laminar and turbulent flow, Fickian diffusion, and forced and free convection is well beyond the scope of this chapter. Discussions relevant to soil and plant surfaces are presented in Chapters 7–9 of Monteith and Unsworth (1990), Chapters 3 and 4 of Rosenberg et al. (1983), and Chapter 3 of Jones (1992). Relevant micrometeorological measurement methods are explained in detail in Chapters 16–21 of Hatfield and Baker (2005). Here we will concentrate on some results and methods of measurement. These methods are valid within the constant flux layer (Figure 6.23), a layer of moving air that develops from the point at which the airstream first reaches a surface of given condition, for example, the wheat field shown in Figure 6.23. The air mixes as it moves over the field, equilibrating with the new surface condition, and forming a layer of gradually increasing thickness, δ_e, within which the vertical flux of heat and vapor is constant with height. This is the fully adjusted or equilibrium layer. Within this layer is a layer, extending from the roughness
elements (wheat plants in this schema) upward, within which air flow is more turbulent due to the influence of the roughness elements. This is called the roughness sublayer (Monteith and Unsworth, 1990). For any measurement of air temperature, humidity, or wind speed, its fetch is the distance upwind from the point of observation to the edge of the new surface. The ratio of the fetch to the value of δ_e is dependent on the roughness of the surface, the stability of the air, and the wind speed. For many crop surfaces, it may be as small as 20:1 or as large as 200:1. For smooth surfaces such as bare soil, the ratio may well be larger than 200:1. See Section 6.2.2.4 for further discussion of fetch. Measurements should be made in the constant flux layer but above the roughness sublayer.

6.2.2.2 Eddy Covariance

The observation of turbulent flow and concept of eddies lead to the EC (also referred to as eddy correlation) method of turbulent flux measurement, including latent heat flux measurement. It has been described as the most physically correct method of providing a direct measurement of the vertical turbulent flux across the mean horizontal streamlines (Swinbank, 1951), provided that fast response sensors (10–20 Hz) are available for the velocity vector and scalar entity of interest. Conceptually, the vertical velocity component (w) of upward moving eddies covaries with a scalar or mass density (s) and the same is true for the vertical velocity component and scalar of downward moving eddies; so, if the instantaneous product ws is on average larger for the upward moving eddies than for the downward moving ones, then the net flux of the scalar or mass of interest is upward. In this method, fast response sensors are used to measure w and s simultaneously at a rate of, for example, 10–20 Hz, producing estimates of the instantaneous deviations w' and s'. This provides an estimate of the vertical flux at the measurement height (but note fetch requirements below). The generic expression for EC can be described as

$$F_s = \overline{w's'},\qquad(6.46a)$$

where

F_s is the flux of a scalar or mass of interest, normally water vapor, sensible heat, or carbon dioxide

w and s are vertical velocity and scalar measurements, respectively

Primes represent instantaneous deviations from a mean and the over bar indicates a time average operator, typically 30 min. With respect to the turbulent fluxes of the energy balance equation, Equation 6.46a can be recast to represent evaporation, LE, and sensible heat, H, fluxes as

$$\text{LE} = \lambda \overline{w'\rho_v'}\qquad(6.46b)$$

$$H = \rho_a c_p \overline{w'T_a'},\qquad(6.46c)$$

FIGURE 6.23 Schematic of sublayers of the surface boundary layer over a wheat crop. The height (h) of the crop and the depth (δ_e) of the constant flux layer are noted. The height (d) is the zero plane displacement height, which is the height to which a logarithmic wind profile, measured above the crop, would extrapolate to zero wind speed.

respectively, where

λ is the latent heat of vaporization

w' has been defined above

ρ'_v is the estimate of instantaneous water vapor density

ρ_a is the density of air

c_p is the specific heat of moist air

T'_a is the estimate of instantaneous air temperature

The rate of data acquisition must be faster for measurements nearer the surface. Monteith and Unsworth (1990) state that eddy sizes increase with surface roughness, wind speed, and height above the surface; and they suggest 1 kHz rates may be needed near a smooth surface, while 10 Hz or less may be adequate at several meters above a forest canopy. Because the measurements should take place within the fully adjusted boundary layer, simply increasing sensor height will not eliminate the need for fast sensor response. EC methods are challenging to conduct due to the data handling and sensor requirements. Data-processing requirements are large, but modern data logging and computing equipment are capable of handling these. Commercial systems including data-processing software are now available, although expensive (Campbell Scientific Inc., Logan, Utah; and The Institute of Ecology and Resource Management at the University of Edinburgh, Scotland). The sonic anemometer is the wind sensor of choice for EC work due its fast response and sensitivity. At this time, a single-axis unit costs about $2500 and a 3D sonic anemometer costs about $8000. Suitable vapor pressure sensors include the krypton hygrometer and infrared gas analyzer (IRGA) available at this writing in the $6,000–$15,000 range.

When LE and *H* are measured by EC, the performance of this approach may be evaluated (Houser et al., 1998) by rearranging Equation 6.1 to

$$LE + H = -R_n - G \tag{6.47}$$

and measuring R_n and *G* (Figure 6.24). This is referred to as evaluating the energy balance closure. If all measurements in Equation 6.47 are perfectly made, then the sum of the turbulent fluxes (LE + *H*) will equal the available energy ($R_n + G$). But in reality, turbulent flux estimates are usually less than the available energy. The degree of energy imbalance is an indication of how well the EC measurements were made. Energy balance closure can also be expressed as the ratio of the sum of the turbulent fluxes to the available energy, where the typical range considered as generally achievable for LE and *H* fluxes is 0.8–0.9.

Fast response thermocouples for measuring air temperature are used in EC systems for measuring *H*. Because these are very much less expensive than fast response vapor pressure sensors, it is sometimes sensible to measure R_n and *G*, and *H* by EC, and to compute LE as the residual

$$LE = -R_n - G - H. \tag{6.48}$$

While EC is in principle a physically correct approach to measuring turbulent flux exchange between a surface and the boundary
FIGURE 6.24 Check of eddy correlation system LE and *H* values against measured R_n and *G* values, all measured at the Walnut Gulch Experimental Watershed, Lucky Hills Site, on days 194–225, 1996. (Adapted from Houser, P.R., C. Harlow, W.J. Shuttleworth, T.O. Keefer, W.E. Emmerich, and D.C. Goodrich. 1998. Evaluation of multiple flux measurement techniques using water balance information at a semi-arid site, p. 84–87. *In* Proc. Spec. Symp. Hydrol. American Meteorological Society, Phoenix, AZ.)

layer of the atmosphere and in practice is relatively straightforward to make, there are a number of important assumptions that must be considered prior to and during data acquisition. These assumptions are well described by Foken and Wichura (1996) and should always be considered prior to any field campaign. Equally important are the corrections applied to the turbulent fluxes after the measurements are made. It is significantly beyond the scope of this chapter to describe in detail the corrections now considered standard for turbulent flux measurements using EC but we list the more important corrections with references. These include coordinate rotation of the velocity and scalar components (Tanner and Thurtell, 1969; Kaimal and Finnigan, 1994; Paw et al., 2000; Wilczak et al., 2001; Lee et al., 2004), the proportionality of a gas concentration to density effects due to changes in temperature and humidity commonly referred to as the WPL correction or adjustment (Webb et al., 1980; Webb, 1982; Leuning, 2004; Massman, 2004), and frequency response and sensor separation corrections (Moore, 1986; Leuning and Judd, 1996; Massman, 2000; Finnigan et al., 2003; Massman and Clement, 2004). All these need to be considered and implemented to ensure the best possible data quality. Note that Thurtell questioned the use of coordinate rotations at a 2002 symposium in his honor.

Despite 40 years of advances in EC equipment and theory since the work of Tanner and Thurtell (1969), including the corrections described above, closure errors of 10%–30% are still common and the error is a systematic underestimation of fluxes, particularly LE and CO_2 fluxes (Twine et al., 2000; Norman and Baker, 2002). This outcome leads one to question either (1) the description of this method by Swinbank (1951) as the most physically correct method of providing a direct measurement of the vertical turbulent flux across the mean horizontal streamlines or

(2) the relevance of such a measurement to determination of LE. Some of the mechanisms possibly causing lack of closure, such as flux divergence and nonstationarity of flow, are intractable, leading Twine et al. (2000) to recommend that closure be forced routinely in order to avoid cumulative errors in flux estimates over time. Closure can be forced either by calculating LE as the residual of Equation 6.1 or by using the measured Bowen ratio; Twine et al. (2000) preferred the latter, but see the next section for possible problems. Comparisons of EC and Bowen ratio systems are found in Dugas et al. (1991) and Houser et al. (1998). Some specifics of EC system design are given in Unland et al. (1996) and Moncrieff et al. (1997).

6.2.2.3 Bowen Ratio

The Bowen ratio is the ratio of sensible to latent heat flux, $\beta_r = H/\mathrm{LE}$ (Bowen, 1926). Introducing this into Equation 6.1 and rearranging gives the Bowen ratio method for estimating LE

$$\mathrm{LE} = \frac{-(R_n + G)}{\beta_r + 1}. \tag{6.49}$$

In the constant flux layer, it is possible to measure temperature and water vapor pressure differences at two heights, z_1 and z_2 and to evaluate β_r from a finite difference form

$$\begin{aligned} \beta_r &= \frac{K_H \rho_a c_p (T_{a\_z_2} - T_{a\_z_1})/(z_2 - z_1)}{K_V (M_w/(M_a P))\rho_a \lambda (e_{a\_z_2} - e_{a\_z_1})/(z_2 - z_1)} \\ &\approx \frac{c_p (T_{a\_z_2} - T_{a\_z_1})}{(M_w/(M_a P))\lambda (e_{a\_z_2} - e_{a\_z_1})} = \gamma \frac{(T_{a\_z_2} - T_{a\_z_1})}{(e_{a\_z_2} - e_{a\_z_1})}, \end{aligned} \tag{6.50}$$

where the second and third entities assume equivalency of the exchange coefficients for sensible heat flux, K_H, and latent heat flux, K_V; and $\gamma = c_p P/(\lambda M_w/M_a)$ is the psychrometric "constant," so-called because its value changes little with temperature, humidity, and normal variations in air pressure. Commonly, values of T_a and e_a are half-hourly or hourly means. Because the sensor response time does not have to be very short, Bowen ratio equipment is much less expensive than that for EC, with complete systems available for under $10,000. Bowen ratio systems are available from REBS, Seattle, Washington; Campbell Scientific, Inc., Logan, Utah, and others.

Because slight differences in instrument calibration may lead to large errors, it is advisable to switch instruments between the measurement heights. The moving arm system popularized by REBS is one way to do this. Bowen ratio measurements are usually valid only during daylight hours. Near sunset and at night, the sum of R_n and G in Equation 6.49 approaches zero even though LE may continue at considerable rates, particularly in advective environments (Tolk et al., 2006), in which most of the irrigated western United States is included. For periods just after sunrise and before sunset, the gradients of

T_a and e_a may become small at the same time that R_n becomes small, leading to instability in Equation 6.50 and irrational estimates of LE. Also near sunset, the value of β_r may approach −1, leading to a near-zero denominator in Equation 6.49 and poorly defined LE (Todd et al., 2000). Bowen ratio systems tend to underestimate LE when regional and local sensible heat advection occurs (Blad and Rosenberg, 1974; Todd et al., 2000), probably because $K_H/K_V > 1$ under the stable conditions that prevail then (Verma et al., 1978). Four Bowen ratio systems were compared by Dugas et al. (1991) who discuss the merits of different designs. Three EC systems agreed well with each other; but LE measurements from them were consistently lower than those from the four Bowen ratio systems. Note that R_n measurement errors can have a large impact on LE calculated using Equation 6.49.

6.2.2.4 Fetch Requirements

Both EC and Bowen ratio methods are sensitive to upwind surface conditions. The LE and H values from these methods represent an areal mean for a certain upwind surface area, often called the "footprint." Both methods require considerable representative upwind surface or fetch, often extending to hundreds of meters, of surface that is similar to that where the measurement is made, if the measurement is to be representative of that surface. Also, the longer the same-surface fetch is, the deeper is the fully adjusted layer, and the higher the instruments can be placed above the surface. Issues of instrument height and fetch are discussed by Savage et al. (1995, 1996) who recommended placing the sonic anemometer of an EC system no closer than 0.5 m above a short grass cover. Because eddies are smaller nearer the surface, placement of the sonic anemometer too near the surface may lead to eddies being smaller than the measurement window of the anemometer. Fetch requirements may be stated as a ratio of fetch distance to instrument height. Heilman et al. (1989) studied fetch requirements for Bowen ratio systems and concluded that a fetch to height ratio of 20:1 was adequate for many measurements, down from the 100:1 ratios reported earlier. Fetch requirements increase as measurement height, z_m, increases. This poses some additional problems for Bowen ratio systems because these incorporate two sensors and the sensors must be sufficiently separated vertically so that the vapor pressure and temperature gradients between them are large enough to be accurately determined. The rougher the surface is, the smaller the gradients are. For many surfaces, and common instrument resolution, this results in separation distances on the order of a meter. The lower measurement should be above the roughness sublayer, typically at least 0.5 m above a crop (more for a very rough surface such as a forest), so the upper measurement may well be nearly 2 m above the crop surface. This could easily lead to a fetch requirement of 100 m. Analysis of relative flux and cumulative relative flux for an alfalfa field under moderately stable conditions using the methods of Schuepp et al. (1990) leads to rather large fetch requirements (Todd et al., 2000; Figure 6.25). For unstable conditions, mixing is enhanced and the boundary
FIGURE 6.25 Relative and cumulative relative flux of an alfalfa field for measurement heights (z_m) of 1 and 2 m, moderately stable thermal conditions, and canopy height of 0.5 m. Cumulative relative flux reaches 0.8 at 65 m for $z_m = 1$ m, and at 225 m for $z_m = 2$ m. (Courtesy of Richard W. Todd, personal communication.)

layer becomes adjusted more quickly over a new surface so that fetch requirements are decreased. However, stable conditions often prevail for irrigated crops in semiarid and arid regions, suggesting that EC and Bowen ratio methods are ill-suited for estimating ET in these settings. Schmid (1997) concluded that fetch requirements are more severe for Bowen ratio than for EC measurements. However, Stannard (1997) argues that Schmid's analysis ignored the gradient measurement approach of Bowen ratio systems and that the fetch requirements are similar for EC and Bowen ratio.

EC methods are sometimes described as making direct measurements of fluxes, and thus are stated to be the only "direct" measure of latent (or sensible) heat flux, particularly of areal extent greater than a few square meters. However, the humidity sensors in EC and Bowen ratio systems do not measure e_a directly, but infer it from measurements of other physical properties, typically light absorption or capacitance changes. Moreover, consideration of fetch requirements leads to a conclusion that both EC and Bowen ratio measurements are representative only for a constantly changing footprint area upwind of the measurement location. The footprint area and the "true" flux are ill-defined because the location and size of the footprint change with wind direction and speed. There is strength in this kind of areal averaging because it reduces noise due to the spatial variability of evaporation. But the measurement cannot be said to be true for any specific location. Indeed, as wind direction changes, the area contributing to the measurement may change completely. By contrast, the soil water balance methods of estimating E, discussed in Section 6.2, provide measures for specific locations. In the case of weighing lysimeters, these are in fact direct measurements of E, specific to a well-defined location, for all times during which precipitation and runoff are not occurring (neglecting the negligible change in plant mass over short periods). Both EC and Bowen ratio measurements are based on the assumption that, within the fully adjusted layer, the vertical mass or energy fluxes are uniform with height, that is, there is no

vertical flux divergence. However, we see from footprint analysis that, for nonzero wind speeds, the upwind area contributes to the measured flux. Even in supposedly uniform fields, there is spatial variability in soil properties and plant responses, so that there is almost always some horizontal flux divergence, and therefore necessarily some vertical flux divergence. Although both methods have been described as "point" measurements, they are really averages over an area, with closer upwind subareas being weighted more heavily and with wind speed and atmospheric stability causing changes in the relative weighting of subareas and the total area involved.

Interest in the spatial variability of the energy balance, particularly the LE component, and in precision farming technologies aimed at addressing crop requirements for water and nutrients at scales well below the field size, has led to a need to measure the spatial variability of LE at scales smaller than can reasonably be addressed with Bowen ratio and EC systems. The radiometric surface temperature can be remotely sensed to provide the spatial variability of LE based on Equations 6.1 and 6.87 (in Section 6.2.4). However, this approach is challenged by difficulties in quantifying surface and aerodynamic resistances and discriminating between crop and soil contributions to the radiometric temperature. There remains a need for ground truth measurements giving LE for a well-defined area. The water balance methods discussed in Section 6.3.1 are capable in many cases, but costs of deployment are practically insurmountable. Thus, there remains a need for inexpensive, accurate, unattended soil profile water content measurement methods for implementation of the water balance method of LE measurement.

6.2.2.5 Field Surface Energy Balance and Remote Sensing

The FSEB has long been recognized for its promise in calculating the latent heat flux, LE, due to ET, from the other energy balance terms in Equation 6.1. When R_n, G, T_s, T_a, h_c, and u_z are measured in the field, Kimball et al. (1999) found that ET (m s^{-1}, positive toward the atmosphere) can be estimated with fair accuracy for full-cover crop surfaces as the residual in

$$\text{ET} = \frac{-\text{LE}}{(\lambda \rho_w)} = \frac{(R_n + G + H)}{(\lambda \rho_w)}, \qquad (6.51)$$

where

$H = \rho_a c_p (T_s - T_a)/r_a$

T_s is assumed equal to the aerodynamic surface temperature, T_o (°C)

r_a is aerodynamic resistance, which is calculated as a function of crop height, h_c, and wind speed, u_z (m s^{-1}), measured at an elevation z (m)

c_p is the heat capacity of air (~1003 kJ kg^{-1} K^{-1})

λ is the latent heat of vaporization (~2.45 × 10^6 J kg^{-1})

ρ_w is the density of water (~1000 kg m^{-3})

ρ_a is air density (kg m^{-3}, $\rho_a \approx 1.291 - 0.00418 T_a$)

In field research, many or all of these fluxes are measured; but from a remote sensing perspective, the surface brightness in the thermal IR (used to estimate T_s) and the brightness in the NIR and visible bands are used to estimate R_n and H. The value of G is taken as a fraction of R_n or some function of R_n and plant cover, which in turn is estimated from a vegetative index based on reflectance in discrete NIR and visible bands. The ET is evaluated as the residual.

Remote sensing–based approaches to FSEB evaluation for ET include both single-surface approaches (e.g., Bastiaanssen et al., 2005; Allen et al., 2007a, 2007b) and two-surface approaches that evaluate the energy and water balances for both canopy and soil surfaces and thus must estimate the crop cover fraction (e.g., Norman et al., 1995; Kustas and Norman, 1999). While providing useful knowledge of regional ET and its spatial and temporal distribution, FSEB predictions that rely on satellite images are not used for infield management due to lack of daily data with sufficient resolution to match appropriate scales for management (Gowda et al., 2008). Attempts to resolve this problem with existing satellite data involve using infrequent, greater resolution data such as that from Landsat (90 m resolution in the thermal IR, 16 d repeat time) in combination with lower resolution more frequent data such as that from MODIS (1000 m resolution in the thermal IR, daily). Such a combination was demonstrated with the DisALEXI (disaggregated atmosphere land exchange inverse) model (Norman et al., 2003; Anderson et al., 2007; Kustas et al., 2007), but no testing of this approach for management has ensued. While aircraft platforms could resolve some of these problems, cost has prevented widespread use of aircraft platforms to provide imaging for management.

The FSEB using remotely sensed data typically provides an instantaneous value of ET, which must be scaled to daily ET using various methods such as the evaporative fraction (which is assumed constant during daylight hours) or reference ET (which is also assumed constant relative to latent heat flux during daylight hours; Colaizzi et al., 2006). Models of the FSEB that use remote sensing include the two-source model (TSM, Norman et al., 1995; Kustas and Norman, 1999), the surface energy balance algorithm for land (SEBAL, Bastiaanssen et al., 1998), and the mapping ET with internalized calibration model (METRIC, Allen et al., 2007a, 2007b). Gowda et al. (2008) reviewed these and several other approaches and reported that daily ET estimation errors ranged from 3% to 35% but that almost all studies compared FSEB ET with ET sensed by Bowen ratio or EC methods, which themselves may have large errors.

Estimates of ET from regional FSEB models using remotely sensed data are often inaccurate for particular field locations due to problems with correctly estimating the surface radiation balance components (Berbery et al., 1999). However, studies using either ground-based or airborne sensor platforms to achieve suitable spatial scales (i.e., a few meters or less), have shown some success with energy balance models for ET (Colaizzi et al., 2003; French et al., 2007).

6.2.2.6 Penman–Monteith Estimates of Latent Heat Flux

Since Penman (1948) published his famous equation describing evaporation from wet surfaces based on the surface energy balance, there have been developments, additions, and refinements of the theory too numerous to mention. Notable examples are the van Bavel (1966) formulation, which includes a surface roughness length term, z_o, and the P–M formula (Monteith, 1965), which includes aerodynamic and surface resistances. The van Bavel equation tends to overestimate in windy conditions and is very sensitive to the value of z_o (Rosenberg, 1969). Howell et al. (1994) compared several ET equations for well-watered, full-cover winter wheat and sorghum and found that the P–M formula performed best. Because it is widely used in agricultural and environmental research, and because it has been presented by ASCE (Jensen et al., 1990; ASCE, 2005) and FAO (Allen et al., 1994a, 1994b, 1998) as a method of computing estimates of reference crop water use, we will discuss the P–M equation, which is expressed as

$$LE = -\frac{\Delta(R_n + G) + \rho_a c_p (e_s - e_a)/r_a}{\Delta + \gamma((1 + r_s)/r_a)}, \qquad (6.52)$$

where

  LE is latent heat flux

  R_n is net radiation

  G is soil heat flux (all in MJ m^{-2} s^{-1})

  Δ is the slope of the saturation vapor pressure–temperature curve (kPa °C^{-1}) commonly evaluated at air temperature

  ρ_a is air density (kg m^{-3})

  c_p is the specific heat of air (kJ kg^{-1} °C^{-1})

  e_a is vapor pressure of the air at reference measurement height z_m

  e_s is the saturated vapor pressure at a dew point temperature equal to the air temperature at z_m (kPa)

  $(e_s - e_a)$ is the vapor pressure deficit

  r_a is the aerodynamic resistance (s m^{-1})

  r_s is the surface (canopy) resistance (s m^{-1})

  γ is the psychrometric constant (kPa °C^{-1})

Penman's equation and those derived from it eliminated canopy temperature from energy balance considerations. Besides measurements of R_n and G, the user must know the vapor pressure of the air, e_a, and air temperature (from which e_s may be calculated) at reference measurement height, z_m (often 2 m). The use of e_s as a surrogate for the (unknown) substomatal vapor pressure introduces the assumptions that osmotic potential of the leaf water has little affect on the substomatal vapor pressure and that the difference between air and canopy temperature does not introduce much error in the estimation of vapor pressure. To the extent that these assumptions are not true, the errors are merged into the resistance terms in Equation 6.52. The values of r_a and r_s may be difficult to obtain. The surface or canopy resistance is known for only a few crops

and is dependent on plant height, leaf area, irradiance, water status of the plants, species, and probably variety.

Jensen et al. (1990) and Allen et al. (1994a, 1994b) presented methods of calculating LE for well-watered, full-cover grass and alfalfa. The following example, drawn from recent studies at Bushland, Texas (Evett et al., 1998, 2000; Todd et al., 2000), employs those methods. Aerodynamic resistance was estimated for neutral atmospheric conditions from

$$r_a = \frac{\ln((z_m - d)/z_{om})\ln((z_H - d)/z_{oH})}{k^2 u_z},$$ (6.53)

where

z_m (m) is the measurement height for wind speed, u_z (m s^{-1})

z_H (m) is measurement height for air temperature and relative humidity

k is 0.41

z_{om} and z_{oH} are the roughness length parameters for momentum (wind) and sensible heat transport

d is the zero plane displacement height

The value of r_a calculated from Equation 6.53 will be too large for highly unstable conditions and too small for very stable conditions. Stability corrections should be made to Equation 6.53 for those conditions (see Monteith and Unsworth, 1990, p. 234 for some examples) but were not made for this example.

Surface resistance was calculated from

$$r_s = \frac{r_l}{(0.5\text{LAI})},$$ (6.54)

where r_l is the stomatal resistance taken as 100 s m^{-1}, and the LAI was taken as

$$\text{LAI} = 5.5 + 1.5\ln(h_c),$$ (6.55)

where the crop height, h_c, was taken as 0.12 cm for grass and 0.5 m for alfalfa.

The zero plane displacement height, d, was calculated as

$$d = \frac{2}{3}h_c.$$ (6.56)

The roughness length for momentum, z_{om}, was calculated as

$$z_{om} = 0.123h_c$$ (6.57)

and the roughness length for sensible heat transport was

$$z_{oH} = 0.1z_{om}.$$ (6.58)
FIGURE 6.26 Daily P–M estimates of ET using both measured and estimated values of R_n and G were not significantly different from each other for well-watered, full-cover mixed fescue grown at Bushland, Texas, in 1996. Both P–M and ET values were less than values measured by a weighing lysimeter for values above 4 mm day^{-1}.

Net radiation was calculated as shown in Section 6.2.1.6. All calculations were on a half-hourly basis. For well-watered mixed fescue grass in 1996, the P–M equation underestimated ET, as measured by a weighing lysimeter, at ET rates exceeding 4 mm day^{-1} (Figure 6.26), even though R_n and G were well estimated. The underestimation of ET was due to systematic error in the surface and/or aerodynamic resistances. For well-watered, full-cover alfalfa in 1996, the P–M estimates of ET were close to values measured with a weighing lysimeter (Figure 6.27). Because R_n and G were well estimated, it is presumed that r_a and r_s were predicted well also. Examination of diurnal dynamics showed that the P–M method was capable of closely reproducing those dynamics.
FIGURE 6.27 Daily P–M estimates of ET using estimated R_n and G for well-watered, full-cover (LAI > 3) alfalfa at Bushland, Texas, in 1996.

Although important as a research model, the P–M method is not much used for direct prediction of LE due to the difficulty of knowing r_a and r_s. However, it is commonly used to predict a theoretical reference ET, ET_o for grass and ET_r for alfalfa, for use in irrigation scheduling (Allen et al., 1994a, 1994b, 1998). In this application, crop water use or ET is estimated from daily values of ET_r and a dimensionless crop coefficient (K_c), which is dependent on the crop variety, crop growth, and the reference ET (ET_o or ET_r) used, and which is often cast as a function of time since planting or growing degree days.

$$ET = K_c ET_r. \qquad (6.59)$$

The crop coefficients are determined from experiments that measure daily crop water use, ET, and that measure or, more commonly, estimate ET_r and then compute

$$K_c = \frac{ET}{ET_r}. \qquad (6.60)$$

Many details on this methodology are found in Jensen et al. (1990) and ASCE (2005).

6.2.2.7 Limitations of the Penman Approximation

At the time that Penman (1948), Monteith (1965), and van Bavel (1966) developed their equations for LE, it was very difficult to measure surface temperature of water or plant canopies. All of these equations are called combination equations because they derive from the combination of the energy balance terms given in Equation 6.1 with heat and mass transfer mechanisms. The transfer mechanisms are usually stated as flux equations in terms of resistance(s) or conductance(s) and a gradient of temperature or vapor pressure from the surface to the atmosphere. Penman (1948) stated Equation 6.1 for a wet surface and used transport mechanisms for LE and H to derive a combination equation

$$LE = f(u)(e_z - e_o^*) = -\left[R_n + G + \gamma f(u)(T_z - T_o) \right], \quad (6.61)$$

where

$f(u)$ is a wind speed dependent conductance or transport coefficient
γ is the psychrometric constant ($c_p P/(0.622\lambda)$)
e_o^* is the saturation vapor pressure at the surface temperature
e_z is the air vapor pressure at measurement height z_m
T_z is the air temperature at measurement height
T_o is the surface temperature
the transport mechanism for H is analogous to Equation 6.89

The equation can use e_o^* because it is assumed that the surface is "wet," that is, a free water surface. With an appropriate choice of $f(u)$, the surface can be the canopy of a crop that is full cover and well supplied with water and thus freely transpiring. Because surface temperature was difficult to measure, Penman (1948) introduced an approximation for $T_o - T_z$ that was derived from
FIGURE 6.28 Quantities used in the derivation of Penman's (1948) combination equation.

the slope of the saturation vapor pressure versus temperature curve (Figure 6.28), which is

$$\Delta = \frac{(e_o^* - e_z^*)}{(T_o - T_z)}. \qquad (6.62)$$

From Equation 6.62 and Figure 6.28, we see that

$$e_o^* - e_z = e_z^* - e_z + \Delta(T_o - T_z). \qquad (6.63)$$

Rearranging to find $(T_z - T_o)$ and substituting into Equation 6.61 gives

$$f(u)(e_z - e_o^*) = -\left[R_n + G + \left(\frac{\gamma}{\Delta}\right) f(u)(e_z - e_o^* + e_z^* - e_z) \right] \qquad (6.64)$$

or

$$f(u)(e_z - e_o^*) = -\left[R_n + G + \left(\frac{\gamma}{\Delta}\right) f(u)(e_z - e_o^*) + \left(\frac{\gamma}{\Delta}\right) f(u)(e_z^* - e_z) \right], \qquad (6.65)$$

both sides of which hold the identity for $LE = f(u)(e_z - e_o^*)$. Rearranging gives

$$LE = -\frac{[\Delta(R_n + G) + \gamma f(u)(e_z^* - e_z)]}{(\Delta + \gamma)}, \qquad (6.66)$$

which is the Penman equation and is analogous to Equation 6.52. Rather than using wind functions of the transport coefficient, Monteith recognized the importance of surface resistance

and derived the equation in terms of the aerodynamic and surface resistances shown in Equation 6.52.

Although there is much evidence that the Penman equation and Equation 6.52 are useful for estimating LE from free water and from well-watered, full-cover crops, the results have been disappointing for transfer of wind functions and r_s and r_a formulations between different regions and crops. Some facts about the underlying assumptions should lend insight. First, the value of Δ is usually evaluated at the air temperature, T_z. In humid climes, there may be little difference between canopy and air temperatures, particularly if skies are often overcast. But in more arid regions, the canopy temperature of a freely transpiring crop may be several degrees cooler than air temperature, causing Δ to be overestimated—more so at the hottest part of the day, when transpiration rates are greatest, than near sunrise and sunset. Second, the net radiation and soil heat fluxes are modified by the quotient $(1 + \gamma/\Delta)$. This is fundamentally incorrect. The value of γ/Δ ranges from 0.80 at 10°C to 0.17 at 40°C; so the modification of R_n and G is not small and will change with air temperature over the course of a day. Third, the surrogate in the Penman equation for sensible heat flux, $\gamma f(u)(e_z^\star - e_z)/(\Delta + \gamma)$, is parameterized by vapor pressure terms defined at the same height. Thus, unlike real sensible heat flux, the surrogate quantity $\gamma f(u)(e_z^\star - e_z)/(\Delta + \gamma)$ can never reverse sign (necessarily, $e_z^\star \geq e_z$). Also, over the range from 10°C to 40°C, the value of γ varies from 65.5 to 67.5 Pa K^{-1}, while the value of Δ varies from 85 to 402 Pa K^{-1}. To the extent that γ is constant, the division of the vapor pressure deficit by $(\Delta + \gamma)$ causes the surrogate term to vary as H would vary. To the extent that the sum $(\Delta + \gamma)$ varies from Δ, and to the extent that $e_z^\star$ differs from $e_o^\star$, the surrogate differs in value from H.

In Equation 6.52, the sum of R_n and G is further modified by the surface and aerodynamic resistances to mass and heat transfer, even though those resistances have negligible effect on the fundamental mechanisms affecting either quantity. (The effect of r_s and r_a on canopy surface temperature has a negligible effect on R_n.) These facts have much to do with the difficulties encountered in determining appropriate values of r_a and r_s and in transferring these values from one region to another. Also, the fact that wind functions for the Penman equation have been determined to be different for different climates is certainly related to the approximations used in the derivation of the Penman and related equations.

At the time that the combination equations were being developed, the instrumentation for measuring net radiation was crude but, compared with that for measuring surface temperature, effective. In the 1960s, the development of infrared radiometers allowed the first radiometric measurements of surface temperature on a large scale, leading to much research on the use of surface temperatures to solve H using forms of Equation 6.89 (see Section 6.2.4), and thus to estimate LE from Equation 6.1. McNaughton (1988) pointed out problems with this method that persist to this day. They include the fact that radiometric surface temperature often differs from aerodynamic surface temperature (the surface temperature that works in Equation 6.89), the difficulty

of evaluating r_a in Equation 6.89 for many surfaces (e.g., partial or mixed canopies), and the spatial heterogeneity of surfaces that leads to spatial heterogeneity of air temperature. However, the continued development of IRTs has led to easy and reliable surface temperature measurement with solid state devices such as the thermocouple IRT (e.g., the model IRt/c from Exergen, Inc.). Meanwhile, the technology for net radiation measurements has improved, but calibration standards do not exist and it is still common to find differences of 10% or more between competing instruments. Just as the lack of adequate instrumentation for measurement of surface temperature affected the development of theory and practice in the mid-twentieth century, the shift in instrumentation capabilities is now affecting much of the experimental physics and development of theory and practice for calculation of surface energy and water balances as discussed in Section 6.2.2.5.

6.2.2.8 Recursive Estimates of Latent Heat Flux

In order to avoid the limitations of the Penman (1948) approximation for $(T_o - T_z)$, several efforts have focused on iterative or recursive solution of the surface energy balance equations, which are implicit in T_o, without resorting to any assumptions. It has long been recognized that only by iterative solution of the implicit energy balance equations can these be solved with complete accuracy (Budyko, 1958; Tracy et al., 1984; McArthur, 1990, 1992; Milly, 1991). Iterative solutions have been used in computer models of the general surface energy balance (Bristow, 1987), of evaporation from bare soil (Lascano and van Bavel, 1983, 1986), and of ET from plant and soil surfaces (Lascano et al., 1987; Evett and Lascano, 1993).

Even though iterative solutions have long been available on personal computers and even possible on hand-held calculators, they have not yet supplanted the P–M approach for calculating reference ET, ET_o, although that is changing. As an alternative to the P–M equation, Lascano and van Bavel (2007) applied a recursive method, attributed to Budyko (1958), in which ET and T_o were found by iteration, satisfying the surface energy balance. Particularly, when $T_a \gg T_o$ and evaporative demand was large, the P–M method underestimated reference ET by as much as 25%. They concluded that the P–M method will underestimate ET in most cases, with the error increasing as evaporative demand increases (larger values of $T_a - T_o$ and smaller values of RH). Widmoser (2009) compared an iterative solution with the P–M method and found the P–M solutions for ET to deviate by as much as −40% to +9% and deviation was greater for smaller time steps (e.g., hourly versus daily). Negative errors were larger when T_a was larger, RH was smaller and the available energy $(R_n + G)$ was smaller. Positive errors increased when RH and T_a were both large while $(R_n + G)$ was small, or when $(R_n + G)$ and T_a were both large and the ratio r_s/r_a was large (large surface resistance and small aerodynamic resistance, for example, tall, stressed plants, and windy conditions).

These analyses give further insight into the problems encountered when transferring crop coefficients between regions with different climates when those K_c values were determined using

P–M based reference ET values. Allen et al. (1994a) provided evidence for this lack of transferability by comparing the estimated ratio of alfalfa to grass reference ET across six arid and five humid locations. The ratio varied considerably across locations, most dramatically between arid and humid locations. For most locations, there was also a difference between the ratio for the peak month and the mean ratio for that location. Note that this variance of ratios applies equally as well to the ratio of a particular crop ET to reference ET (i.e., the crop coefficient, ET/ET_r) thus calling into question the transferability of crop coefficients. Evett et al. (2000) compared alfalfa and grass P–M reference ET formulas to measured ET for alfalfa and grass grown under reference ET conditions and found that the ratio of alfalfa to grass reference ET was not well predicted by the P–M formulations for their windy, semiarid advective environment, thus supporting the findings of Allen et al. (1994a). Shuttleworth (2006) presented an analysis of K_c as used with the P–M method in which he showed that K_c values depend explicitly on the climatic conditions at the time of K_c determination. For a variety of different plant heights and canopy resistances, Annandale and Stockle (1994) used an energy balance model to study variability of full-canopy-cover K_c, as influenced by changes in solar radiation, air temperature, the vapor pressure deficit ($e_z − e_o^*$), and wind speed. Variability in K_c increased as crop height increased and as r_s decreased. Variability in K_c decreased if an alfalfa reference ET was used rather than a grass reference ET; and they recommended (1) using alfalfa reference ET and (2) development of methods for directly estimating crop ET. In light of the discussion in Sections 6.2.2.7 and 6.2.2.8, we add to this list a recommendation to pursue a reference ET based on iterative solution of the energy balance equations.

6.2.2.9 Bare Soil Evaporation Estimates

Evaporation from bare soil (E_S) may be estimated using the EC and Bowen ratio methods previously described with consideration given to the reduced surface roughness of many bare soil surfaces when compared with vegetated surfaces. Also, Section 6.3 describes measurements of E_S using weighable lysimeters of various sizes. Here we describe some alternatives based on energy balance solutions.

Fox (1968) and later Ben-Asher et al. (1983) and Evett et al. (1994) described a bare soil evaporation (E_S) prediction method based on subtracting the energy balance equations (Equation 6.1) written for a dry and a drying soil. Because E_S is zero for a dry soil, this gives an expression for E_S from the drying soil in terms of the other energy balance terms. The method requires a column of dry soil embedded in the field of drying soil and measurements of the surface temperatures of the dry soil and of the drying field soil. The surface temperature difference between the dry and drying soils explains most of E_S, but prediction accuracy is only moderately good ($r^2 = 0.82$ for daily predictions, Evett et al., 1994). Evett et al. showed that the aerodynamic resistance over the dry soil surface was reduced and that the resistance was relatively independent of wind speed, probably due to buoyancy of air heated over the relatively hot, small surface. They also

showed that consideration of the soil albedo change with drying could improve the E_S estimates. Qiu et al. (1999) replaced the aerodynamic resistance with a soil evaporation transfer coefficient: $h_a = (T_s − T_a)/(T_d − T_a)$, where T_s is the surface temperature of a drying soil, T_d is the surface temperature of a dry soil, and T_a is air temperature. They found good agreement dynamically, although their model consistently overestimated soil E_S by 5%. Although the method shows promise, it does not provide an estimate of surface soil water content that would be needed to calculate the albedo change.

When soil is wet, the evaporative flux can be estimated using the Penman or P–M equations with surface resistance set to an appropriate low value (Howell et al., 1993). This wet period is the energy-limited stage of evaporation. As the soil dries, E_S becomes limited by soil properties. Van Bavel and Hillel (1976) addressed this using a finite difference model of soil water and heat flux that later was developed into the CONSERVB model of evaporation from bare soil (Lascano and van Bavel, 1986). This model described 1D soil water movement with Darcy's law, including the dependence of hydraulic conductivity, K (m s^{-1}), on soil water potential, h (m), and the soil water retention function, $θ_v(h)$. The surface energy balance was solved implicitly for surface temperature (T_s), resulting in calculated values of E_S, H, R_n, and G at each time step. The value of E_S was used as the upper boundary condition for soil water flux at the next time step. The elements of CONSERVB were included in the ENWATBAL model by Lascano et al. (1987) who included a vapor transport algorithm as a function of soil drying. The latter model was upgraded to model albedo changes dependent on surface soil water content by Evett and Lascano (1993). The 1993 version of ENWATBAL was shown to more accurately predict E_S than either the Penman or P–M equations (Howell et al., 1993). These detailed models of the soil–plant–atmosphere continuum include numerical simulation of soil heat and water fluxes that depend on detailed information on the soil hydraulic properties (characteristic curves) and property changes with depth.

Kustas (2002) summarizes the bulk transport approaches to E_s estimation that depend on the vapor pressure gradient between the soil surface and the air and may include a drying front algorithm; and he contrasts these more mechanistic approaches with several analytical methods that involve a bulk soil resistance and are more amenable to inclusion in models using remotely sensed data for large area estimation of evaporation.

6.2.2.10 Transpiration

Transpiration, the water evaporated from the plants primarily through stomata, is a significant contributor to total latent heat flux and is directly related to the total dry matter production of plant communities (de Wit, 1958). Methods of determining transpiration (E_T) vary widely. The simplest approach has been to weigh single plants in sealed containers (Briggs and Shantz, 1913, 1914). Canopy level measurement of the total evaporative flux (ET) using such methods as lysimetry, Bowen ratio, and EC requires that soil water evaporation (E_S) be determined, so that E_T can be estimated as the residual, or $E_T = ET − E_S$.

The E_S component may be measured using soil microlysimeters (see Section 6.3.1). This is the most direct method of determining E_T without sealing the soil surface.

Another method has been to estimate E_T using equations based on the surface energy balance and gradients in water vapor concentrations and resistances to vapor and heat exchange between the plant canopy and the air. A representative equation is the widely used P–M formula (1965). The difficulty in using such equations is derivation of bulk canopy resistances to vapor and heat transport that also exclude contributions from the soil. One approach to measure canopy resistance has been to first make stomatal resistance measurements on a portion of a leaf using a porometer (Turner, 1991) or gas analyzer system (Rochette et al., 1991). The measurement strategy must somehow capture the totality of the water loss from the plant canopy as affected by differences in leaf illumination, leaf angles, microclimates, and aerodynamic resistances throughout the canopy. The stratified measurements must then be integrated to a whole canopy resistance, which is a process that has met with limited success (Baldocchi et al., 1991; Rochette et al., 1991). The bulk aerodynamic resistance must also be correctly estimated for the P–M equation, which is also complicated by its possible interactive relationship with bulk canopy resistance (Paw and Meyers, 1989). Furon et al. (2007) used numerical simulations to assess the leaf-to-canopy scale translation of surface resistances and their impact on the performance of the P–M equation. Raupach and Finnigan (1988) investigated both single- and multilayer models of evaporation.

Because of these difficulties, techniques to measure plant sap flow as an approximation of whole plant transpiration have advanced. Sap flow measurement systems use the application of heat to the plant stem to serve as a tracer of the sap movement through the xylem tissue. Currently, there are three groups of heat systems to determine sap flow: stem heat balance, heat dissipation, and heat pulse (Gonzalez-Altozano et al., 2008). The stem heat balance method is the most suitable method for herbaceous annual plants with smaller stem diameters, while the heat pulse and heat dissipation methods are primarily used for woody plants, especially those with large trunk diameters. In the stem heat balance method, a heater strip constantly heats a small section of the entire plant stem, and temperature sensors below and above the strip measure how much heat is moved away from the region by the sap. The specific heat capacity and density of the sap are then used to convert the measurements into volumetric mass sap flow. Over- or underestimating sap flow can occur during periods of small or large flow rates. The heat pulse and heat dissipation methods use probes inserted into the stem, with the heat applied either as a pulse or at a constant rate. Temperature sensors in the probes determine sap velocity. Probe location and cross-sectional area and geometry of the stem must be accounted for to extrapolate probe measurements into whole plant sap flow for both methods, and calibration may be required. In all methods, a strategy for transforming single plant measurements to field scale E_T must be developed. Commonly used strategies include weighting by leaf area or stem or trunk diameter (Cohen and Li, 1996).

6.2.3 Soil Heat Flux

Soil heat flux is discussed in detail in Chapter 9. Additional information related to the surface energy balance is given here. Briefly, heat conduction in one dimension is described by a diffusion equation:

$$C\frac{\partial T}{\partial t} = k_T \frac{\partial}{\partial z}\left[\frac{\partial T}{\partial z}\right], \qquad (6.67)$$

where the volumetric heat capacity, C (J m^{-3} K^{-1}), and the thermal conductivity, k_T (J s^{-1} m^{-1} K^{-1}), are assumed constant in space; and vertical distance is denoted by z, time by t, and temperature by T.

The 1D soil heat flux, G, for a homogeneous medium is described by

$$G = -k_T \frac{\partial T}{\partial z}. \qquad (6.68)$$

The thermal conductivity is a single-valued function of water content and is related to the thermal diffusivity, D_T (m^2 s^{-1}), by

$$k_T = D_T C, \qquad (6.69)$$

where the volumetric heat capacity, C (J m^{-3} K^{-1}), can be calculated with reasonable accuracy from the volumetric water content, θ_v (m^3 m^{-3}), and the soil bulk density, ρ_b (Mg m^{-3}), by

$$C = \frac{2.0 \times 10^6 \rho_b}{2.65} + 4.2 \times 10^6 \theta_v + 2.5 \times 10^6 f_o \qquad (6.70)$$

for a soil with a volume fraction, f_o, of organic matter (Hillel, 1980).

Table 6.6 lists thermal conductivities at "wet" and "dry" points for several soils. For coarse soils, the thermal conductivity versus water content curve is S-shaped (see e.g., Campbell et al., 1994), with a rapid rise at water contents corresponding to about 33 kPa soil water tension (about "field capacity"). For fine soils, the relationship is more linear; and the thermal conductivity between dry and wet conditions in Table 6.6 can be linearly interpolated from the values given, with reasonably small errors. But for water contents below the "dry" value, the thermal conductivity should be taken as the value corresponding to the "dry" state.

De Vries (1963) developed a method of estimating soil thermal conductivity from soil texture, bulk density, and water content. The method, while including most important soil properties affecting conductivity, is limited in that it requires knowledge of parameters called shape factors that describe how the soil particles are packed together. The shape factors are specific to a given soil and perhaps pedon and must be measured. They are, in effect, fitting parameters (e.g., Kimball et al., 1976). De Vries' method tends to overestimate thermal conductivity at

water contents above about 0.15 (Asrar and Kanemasu, 1983; Evett, 1994). Campbell et al. (1994) developed modifications of de Vries' theory that allowed them to match measured values well. They showed that, as temperature increased, the thermal conductivity versus water content curve assumed a pronounced S-shape for the eight soils in their study, with the curve deviating from monotonicity at temperatures above 50°C.

Horton et al. (1983) developed a measurement method for D_T based on harmonic analysis. The method entailed fitting a Fourier series to the diurnal soil temperature measured at 1 h intervals at 0.01 m depth followed by the prediction of temperatures at a depth, z (0.1 m), based on the Fourier series solution to the 1D heat flux problem using an assumed value of D_T. The value of D_T was changed in an iterative fashion until the best fit between predicted and measured temperatures at z was obtained. The best fit was considered to occur when a minimum in the sum of squared differences between predicted and measured temperatures was found (i.e., minimum sum of squared error, [SSE]). Poor fits with this and earlier methods are often due to the fact that field soils usually exhibit increasing water content with depth and changing water content with time, while the method assumes a homogeneous soil. Costello and Braud (1989) used the same Fourier series solution and a nonlinear regression method, with diffusivity as a parameter to be fitted, for fitting the solution to temperatures measured at depths of 0.025, 0.15, and 0.3 m.

Neither Horton et al. (1983) nor Costello and Braud (1989) addressed the dependency of diffusivity on water content or differences in water content between the different depths. Other papers have dealt with thermal diffusivity in nonuniform soils but did not result in functional relationships

between thermal properties and water content, probably due to a paucity of depth-dependent soil water content data (Nassar and Horton, 1989, 1990). Soil water content often changes quickly with depth, time, and horizontal distance. Moreover, diffusivity is not a single-valued function of soil water content and so is difficult to directly use in modeling. The ability of time domain reflectometry (TDR) to measure water contents in layers as thin as 0.02 m (Baker and Lascano, 1989; Alsanabani, 1991) provided the basis for design of a system that simultaneously measures water contents and temperatures at several depths.

Evett (1994) used measurements of soil temperature at several depths (e.g., 2, 4, 6, 8 … cm), coupled with TDR measurements of soil water content at the same depths, to find a relationship between thermal conductivity and water content in a field soil. He used the minimum SSE method of Horton to find the thermal diffusivity for each soil layer between vertically adjacent measurements of water content and temperature. The water content for this layer was used to calculate C and thus λ corresponding to that water content. A function of k_T versus θ_v was developed by regression analysis on the k_T and θ_v data (Figure 6.29). Because both C and k_T were known for each layer, this method also gave the soil heat flux.

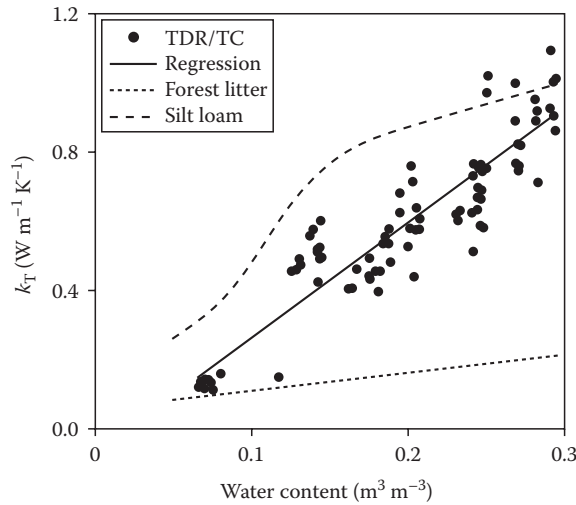
The complicated methods of measuring thermal diffusivity and conductivity mentioned here use computer programs and nonlinear regression fitting of multiterm sine series in order to handle diurnal temperature waves that differ from simple sinusoidal waves, as well as to incorporate measurements of soil water content that vary with depth. However, rough estimates of the thermal parameters may be made from phase differences and amplitude differences observed for temperatures measured


FIGURE 6.29 Thermal conductivity (k_T) of Pullman silty clay loam, determined from TDR probe and thermocouple arrays, compared with functions from Campbell (1985) for forest litter and silt loam.

FIGURE 6.30 Temperatures at six depths in a Pullman clay loam for 2 days in 1993.

at only two depths, with the application of simplifying assumptions of homogeneous water content and soil properties, and a simple sinusoidal diurnal temperature wave describing the temperature T at depth z and time t

$$T(z,t) = \overline{T} + A_z \sin[\omega t + \phi(z)], \qquad (6.71)$$

where
$\overline{T}$ is the mean temperature (i.e., the mean of maximum and minimum for a sine wave)
A_z is the amplitude of the wave (i.e., the difference between maximum and minimum temperatures)
ω is $2\pi/\tau$, where τ is the period (e.g., 24 h)
$\phi(z)$ is the phase angle at depth z (difference in time between the occurrence of the maxima or minima at depth 0 and depth z, units of radiance)

Equation 6.67 can be solved using the above equation for $T(z, t)$ yielding

$$T(z,t) = \overline{T} + \frac{A_0 \sin[\omega t - (z/z_d)]}{e^{z/z_d}}, \qquad (6.72)$$

where
A_0 is the amplitude at depth zero
z_d is called the damping depth and is a function of the thermal conductivity and volumetric heat capacity

$$z_d = \left(\frac{2k_T}{C\omega}\right)^{1/2}. \qquad (6.73)$$

When z equals z_d, the amplitude is $1/e = 0.37$ of the amplitude at depth zero. Writing Equation 6.72 for two depths, z_1 and z_2, and solving for k_T/C gives

$$\frac{k_T}{C} = \frac{\pi(z_2 - z_1)^2}{\tau[2.3\log(A_1/A_2)]^2}. \qquad (6.74)$$

Figure 6.30 shows measured diurnal temperature waves for several depths in a Pullman clay loam on two different days. Table 6.7 gives the mean water content as measured by TDR for each depth. Also shown are the thermal conductivities obtained by fitting a sine series to each depth and evaluating the thermal conductivity of the layer between depths by using the coefficients of the sine series in a sine series solution to $T(t)$ at the next depth and then performing a nonlinear fit of that solution to obtain the thermal conductivity.

Single-probe heat pulse methods have been developed to measure thermal diffusivity; and a dual-probe heat pulse method (Campbell et al., 1991) can measure the thermal diffusivity, D_T, as well as k_T and C (Kluitenberg et al., 1995). Noborio et al. (1996) demonstrated a modified trifilar (three-rod) TDR probe that measured θ_v by TDR, and k_T by the dual probe heat pulse method. Their measured k_T compared well with values calculated from de Vries (1963) theory.

Soil heat flux is more commonly determined using heat flux plates (Table 6.1). These are thermopiles that measure the temperature gradient across the plate, and, knowing the conductivity of the plate, allow calculation of the heat flux from Equation 6.74. Heat flux plates are impermeable and block water movement. Because of this, the plates should be installed a minimum of 5 cm below the soil surface, so that the soil above the plate does not dry out or wet up appreciably more than the surrounding soil. Typical installation depths are 5 or 10 cm. Even at these shallow depths, the heat flux is greatly reduced from its value at

FIGURE 6.31 Four methods of correcting heat flux, measured with plates at 5 cm depth, to surface heat flux.

the soil surface; and corrections must be applied to compute surface heat flux. The most common correction involves measuring the temperature and water content of the soil at midlayer depths, z_j, in N layers (j to N) between the plate and surface and applying the combination equation over some time period, τ_t, defined by beginning and ending times t_i and t_{i+1}

$$G = G_z + \frac{\sum_{j=1}^{N}(T_{zj\_i+1} - T_{zj\_i})\Delta z_j C_{zj}}{(t_{i+1} - t_i)}, \quad (6.75)$$

where

    G is the surface heat flux during τ_t
    G_z is the flux at depth z
    T_{zj} are temperatures at the N depths, z_j, at times t_i and t_{i+1}
    Δz_j is the depth of the layer with midpoint z_j

where the volumetric heat capacities, C_{zj}, at depths z_j are calculated from Equation 6.70, rewritten as

$$C_{zj} = \frac{2.0 \times 10^6 \rho_{bzj}}{2.65} + 4.2 \times 10^6 \theta_{vzj} + 2.5 \times 10^6 f_{ozj}, \quad (6.76)$$

where θ_{vzj}, ρ_{bzj}, and f_{ozj} are the water contents, soil bulk densities, and volume fractions of organic matter, respectively, at depths z_j. The estimate of G is not much changed by the exact form of the combination equation as shown by data from Bushland, Texas, for four forms of Equation 6.75 (Figure 6.31). For situations where water content and temperature change rapidly with depth, or bulk density or f_o changes rapidly with depth, the multiple layer approach will work better.

As an example, we compare four methods of combining temperature and water content data to correct heat flux for bare soil at Bushland, Texas, in 1992 (Figure 6.31). Temperatures were measured at 2 and 4 cm depths (two replicates) with thermocouples, T_2 and T_4; at the surface with a single IRT, T_0; and as a mean temperature of the surface to 5 cm depth soil layer using thermocouples wired in series and buried (four replicates) at 1 and 4 cm depths, T_{1_4}. Water contents were measured by TDR probes (two replicates) inserted horizontally at 2 and 4 cm depths, θ_2 and θ_4. Soil heat flux at 5 cm depth, G_5, was measured with heat flux plates (four replicates). For all methods, the product of soil bulk density and heat capacity of soil solids were set to 1.125 MJ m⁻³. For the first method, the surface heat flux, G_0, was described as

$$G_0 = G_5 + \frac{(1.125 + 4.2\theta_w) \times 10^6 (0.05)(T_{w+1} - T_w)}{1800}, \quad (6.77)$$

where 1800 was the period in seconds; the weighted water content for the surface to 5 cm depth layer, θ_w, was

$$\theta_w = \frac{3\theta_2}{5} + \frac{2\theta_4}{5} \quad (6.78)$$

the weighted temperature for the surface to 5 cm depth layer, T_w, was

$$T_w = \frac{3T_2}{5} + \frac{2T_4}{5} \quad (6.79)$$

and T_{w+1} was calculated the same way, but for the previous measurement.

For the second method, θ_w and the series-wired thermocouple temperature were used:

$$G_0 = G_5 + \frac{(1.125 + 4.2\theta_w) \times 10^6 (0.05)(T_{1\_4+1} - T_{1\_4})}{1800}. \quad (6.80)$$

For the third method, θ_w was used:

$$G_0 = G_5 + \frac{(1.125 + 4.2\theta_w) \times 10^6 (0.05)(T_{024+1} - T_{024})}{1800}, \quad (6.81)$$

but the depth-weighted mean, T_{024}, of IRT temperature and the temperatures measured at 2 and 4 cm was used.

$$T_{024} = \frac{\left[\dfrac{(T_0 + T_2)/2 + T_0}{2}\right]}{5} + \frac{2T_2}{5} + \frac{2T_4}{5}. \quad (6.82)$$

For the fourth method, a modified layer approach was used:

$$G_0 = G_5 + \frac{(1.125 + 4.2\theta_2) \times 10^6 (0.05)(T_{02+1} - T_{02})}{1800}$$
$$+ \frac{(1.125 + 4.2\theta_4) \times 10^6 (0.05)(T_{4+1} - T_4)}{1800}. \quad (6.83)$$

where the depth-weighted mean temperature in the surface to 3 cm deep layer, T_{02}, was

$$T_{02} = \frac{\left[\dfrac{(T_2 + T_0)/2 + T_0}{2}\right]}{3} + \frac{2T_2}{3}. \quad (6.84)$$

All of these methods produced similar values of G_0, but those using a depth-weighted water content tended to overestimate extreme values, probably because the 2 cm water content was less than that at 4 cm (Figure 6.31). The weighted mean approach for both water content and temperature, with surface temperature included (Equation 6.81), produced generally the largest diurnal swing in G_0. Methods that did not include the surface temperature, but used the weighted mean approach for both water content and temperature (Equations 6.77 and 6.80), produced intermediate results. The layer approach (Equation 6.83), produced the smallest diurnal swing in G_0, despite using the surface temperature, and is probably the most accurate approach. All methods corrected both the amplitude and the phase of the diurnal cycle of G_0 appropriately.

Spatial variability of G can be considerable due to shading of soil by vegetation and due to micro-relief that both lead to variable soil wetness, thermal conductivity, and E_s rates.

For row crop investigations, at least four soil heat flux plates should be used to obtain a representative mean. Spatial and temporal variation of G will depend on row orientation, crop height and cover factor, and the time since wetting and the pattern of soil water uptake by roots. For sparse canopies, G measurement may require many more heat flux plates (Kustas et al., 2000).

6.2.3.1 Bernoulli, Soil Air, and Convective Heat Flux

In addition to diffusive heat flux, convective heat flux plays an important and often overlooked role in soil heating or cooling. This is the heat transported by moving air or water, the latter denoted in Figure 6.1 by G_{Jw} for heat transported by infiltrating water. Convective heat flux due to infiltration of water can be much larger than that due to diffusion on a diurnal basis. For example, irrigation with 5 cm of water at 15°C on a soil at 25°C with an initial water content of 0.1 m³ m⁻³ and a bulk density of 1.48 would immediately lower the temperature of the 11.6 cm deep, wetted layer to 20°C (assuming negligible heat of wetting, the soil brought to saturation, and a heat capacity of 1.54 MJ m⁻³ K⁻¹). Although soil temperature may be changed strongly by infiltration of water, there is another mechanism for soil temperature changes, the heat of wetting. The heat of wetting is heat energy released when a soil is wetted and is usually not large enough to be important in heat balance calculations. It can be large for clays with large surface area if they are extremely dry, ranging from 40 J g⁻¹ for kaolinitic clays to 125 J g⁻¹ for allophanic clays (Iwata et al., 1988). But, it decreases quickly as the initial water content of the soil increases and is not likely to be important for the normal range of field water contents.

Convective heat flux due to air movement into and out of soil surfaces is commonly ignored in energy balance considerations. Most people do not see any reason for air to move into or out of soil other than changing atmospheric air pressure. However, there are other forces at play that may significantly increase air flow into or out of soil surfaces. Consider Bernoulli's theorem,

$$\frac{v_1^2}{2g} + \frac{p_1}{\rho_a g} + z_1 = \frac{v_2^2}{2g} + \frac{p_2}{\rho_a g} + z_2, \quad (6.85)$$

which is an equation of conservation of energy where v_1 and v_2 are fluid (e.g., air) velocities at two points, p_1 and p_2 are the respective fluid pressures normal to the fluid flow direction, ρ_a is the density of air, g is the acceleration due to gravity, and z_1 and z_2 are the elevations of the two points. Placing point 1 in the soil and point 2 in the atmosphere directly above the soil, we see that $v_1 \approx 0$, and $v_2 \geq 0$, so that the equation may be rewritten as

$$p_1 - p_2 = \frac{\rho_a v_2^2}{2} + (z_2 - z_1)\rho_a g. \quad (6.86)$$

That is, the pressure differential from soil to air is equal only to the elevation difference multiplied by $\rho_a g$ when wind speed is zero, and it increases above that value as the square of wind speed. During sustained winds across flat surfaces, there is a

sustained pressure gradient driving air movement from soil to air. For air movement over nonplanar surfaces, the situation is complicated by other aerodynamic effects such as drag, which may increase or decrease the pressure gradient at various places over the surface. This has implications for soil gas efflux rates and measurements (Rudolf et al., 1996). Turbulent air flow across soil was investigated by Farrell et al. (1966), who showed with field measurements and theoretical analysis that the effective gaseous diffusion coefficient in soil could be increased by 100 times for wind speed of $7\,m\,s^{-1}$. Bulk air movement into and out of soils can substantially alter the energy balance as evidenced by such phenomena as ice caves in permeable lava rocks overlain by soils.

6.2.4 Sensible Heat Flux

Sensible heat flux is the transfer of heat energy away from or to the surface by conduction or convection. Because air is a poor conductor of heat, most sensible heat flux is by convection (movement) of air. This occurs in eddies of different scales depending on the turbulence of the atmosphere near the surface. Turbulence is influenced by the aerodynamic roughness of the surface, the wind speed, and the temperature differential between the surface and the air. Perhaps the most common method of evaluating sensible heat flux is to measure the other terms in Equation 6.1 as accurately as possible and then set H equal to the residual

$$H = -R_n - G - LE. \qquad (6.87)$$

Of course, this approach lumps all the errors in the other terms into H. More importantly, it does not allow for a check on the accuracy of the energy balance. By definition, if H is defined by Equation 6.87 then Equation 6.1 will sum to zero. Only an independent measure of H can provide a check sum for Equation 6.1. As noted in Section 6.2.2.2, EC is a direct method of measuring H.

The Bowen ratio method can be applied to sensible heat flux as well as to latent heat flux as outlined in Section 6.2.2.3. Sensible heat flux is calculated from the Bowen ratio as (following Rosenberg et al., 1983, p. 256)

$$H = \frac{-(R_n + G)}{(1 + (1/\beta_r))}. \qquad (6.88)$$

The considerations of fetch, measurement height, equipment, etc., mentioned in Section 6.2.2.4 for Bowen ratio and EC measurements apply as well to sensible heat flux measurements made with these methods.

Though obviously a dynamic and complex process, sensible heat flux, H ($W\,m^{-2}$), is sometimes estimated using a straightforward resistance equation

$$H = \frac{\rho_a c_p (T_z - T_0)}{r_{aH}}, \qquad (6.89)$$

where

ρ_a is the density of air ($\rho_a = 1.291 - 0.00418 T_a$, with less than $0.005\,kg\,m^{-3}$ error in the $-5°C$ to $40°C$ range, T_a in °C)

c_p is the heat capacity of air ($1.013 \times 10^3\,J\,kg^{-1}\,K^{-1}$)

T_z is the air temperature at measurement height

r_{aH} is the aerodynamic resistance to sensible heat flux ($s\,m^{-1}$)

T_0 is the temperature of the surface

For vegetation, the "surface" for aerodynamic resistance is the height at which the logarithmic wind speed profile, established by measurements of wind speed above the surface, extrapolates to zero. This height is $d + z_{om}$ and is often well below the top of the canopy, typically at 2/3 to $3/4 h_c$. Measurements of surface temperature (with, for instance, an IRT) may not be the mean temperature at the same height as the aerodynamic "surface," thus introducing bias in the r_{aH} estimation. Also, the roughness length for momentum, z_{om}, may be different from that for sensible heat, z_{oH}.

A general form for aerodynamic resistance to sensible, latent energy, and momentum fluxes is

$$r_a = \frac{1}{k^2 u_z} \left[\ln\left(\frac{z_m - d}{z_o}\right) \right]^2, \qquad (6.90)$$

where

k is the von Kármán constant = 0.41

z_o is the roughness length (m)

z_m is the reference measurement height (m)

u_z is the wind speed ($m\,s^{-1}$) at that height

d is the zero plane displacement height (m)

Equation 6.90 only holds for neutral stability conditions. Unstable conditions occur when the temperature (and thus air density) gradient from the surface upward is such that there is warm air rising through the atmosphere (forced convection). Stable conditions prevail when the air is much cooler and denser near the surface, thus inhibiting turbulent mixing due to forced convection. Neutral conditions obtain when neither stable nor unstable conditions do.

For bare soil, Kreith and Sellers (1975) simplified Equation 6.90 as follows:

$$r_a = \frac{1}{k^2 u_z} \left[\ln\left(\frac{z_m}{z_o}\right) \right]^2. \qquad (6.91)$$

They found a value of $z_o = 0.003\,m$ worked well for smooth bare soil.

For nonneutral conditions, a variety of stability corrections have been proposed. See Rosenberg et al. (1983, pp. 140–144) and Monteith and Unsworth (1990, pp. 234–238). Because many models of the soil–plant–atmosphere continuum use Equation 6.89 to model H, it is important to note that, while stability corrections can improve model predictions of H and surface

temperature, the stability corrections are implicit in terms of H. This leads to a requirement for iterative solution of sensible heat flux at each time step in these models.

Knowledge of appropriate values for d and z_o in the above equations can be hard to come by since their determination involves measurements of wind speed and temperature at multiple heights within and above the canopy (Monteith and Unsworth, 1990). Campbell (1977) suggests estimating these from plant height, h_c, as

$$d = 0.64h_c \qquad (6.92)$$

for densely planted agricultural crops and

$$z_{om} = 0.13h_c \qquad (6.93)$$

for the roughness length for momentum for the same condition. Campbell (1977) gives the roughness length parameters for sensible heat, z_{oH}, and vapor transport, z_{ov}, as

$$z_{oH} = z_{ov} = 0.2z_{om}. \qquad (6.94)$$

Note that Equation 6.94 differs from Equation 6.58, where Jensen et al. (1990) used $z_{oH} = 0.1\,z_{om}$. For coniferous forest, Jones (1992) gives

$$d = 0.78h_c \qquad (6.95)$$

and

$$z_{om} = 0.075h_c \qquad (6.96)$$

for these parameters. As wind speeds increase, many plants change form and height, with resulting decrease in h, d, and z_{om}. It is unlikely that the relationships given in Equations 6.92 through 6.96 hold true for large wind speeds.

6.3 Water Balance Equation

The water balance equation is written for a control volume of unit surface area and with a vertical dimension that extends from the soil surface to a lower boundary that is commonly assigned a depth below the bottom of the root zone (Figure 6.1) but may be much deeper:

$$0 = \Delta S - P + R - F - \frac{LE}{(\lambda \rho_w)}, \qquad (6.97)$$

where
   ΔS is the change in soil water storage in the profile (taken as positive when water storage increases over time)
   P is precipitation and irrigation
   R is the sum of runoff and runon
   F is flux across the lower boundary of the profile
   $LE/(\lambda \rho_w)$ is water lost to the atmosphere through evaporation from the soil or plant or gained by dew formation

Units are typically millimeter depth of water per unit time, equivalent to volume of water per unit area per unit time. The value of P is always positive or zero, but values of ΔS, R, F, and $LE/(\lambda \rho_w)$ may have either sign. By convention, R is taken to be positive when there is more runoff than runon. As in Equation 6.1, $LE/(\lambda \rho_w)$ is positive when flux is toward the surface of the soil. The equation is often rearranged to provide values of $LE/(\lambda \rho_w)$ when suitable measurements or estimates of the other terms are available; but it can and has been used to estimate runoff, soil water available for plants, and deep percolation losses (flux downward out of the control volume). Here, we take F as positive when flux is upward across the lower boundary into the control volume. The term F is used rather than P for deep percolation, both to avoid confusion with precipitation, and to avoid the common misconception that deep flux is only downward since P is often used to indicate deep percolation.

In the case of $LE/(\lambda \rho_w)$, the units of LE (W m^{-2}) are conveniently converted to depth of water in mm s^{-1} by dividing by the latent heat of vaporization (λ, ~2.45 × 10^6 J kg^{-1}) and by the density of water (ρ_w, ~1000 kg m^{-3}), with little loss of accuracy because the changes in density of water and the latent heat of vaporization with temperature are small. For precise work, both parameters can be temperature corrected. The change in storage (ΔS) is often determined by measuring soil water content changes by methods that give volumetric water content, θ_v (m^3 m^{-3}). Multiplying the water content by the depth of the layer gives the depth of water stored, and the first derivative of storage over time is ΔS. In the United States, the term ET is used to represent the sum of evaporative fluxes from the soil and plant. By convention, ET is taken as positive for fluxes from plant or soil surface to the atmosphere. Thus, ET = $-LE/(\lambda \rho_w)$ and the water balance may be rearranged as

$$\Delta S = P - R + F - \text{ET}. \qquad (6.98)$$

This provides a use for the ET term for those who prefer to say evaporation rather than ET. Examination of Equation 6.98 will satisfy the reader that soil water storage increases with precipitation, decreases if runoff from precipitation occurs, decreases with increasing ET, and increases with flux upward into the control volume. Although Equations 6.97 and 6.98 are instantaneous rate equations, they are often written for an assumed period of time such that the variables are in units of depth of water for that time period.

6.3.1 Measuring ΔS and ET

Probably the most accurate method of measuring ΔS is the weighing lysimeter (Wright, 1991). Although large weighing lysimeters involve considerable expense, they can give very precise measurements (0.05 mm = 0.05 kg m^{-2}) (Howell et al., 1995). An excellent review of the use of weighing lysimeters is given by Howell et al. (1991). Careful design, installation, and operation will overcome any of the serious problems reported with some lysimeters including disturbance of the soil profile (less with monolithic lysimeters),
FIGURE 6.32 Cross-sectional view of simplified weighing lysimeter installed for grass reference ET measurements at Bushland, Texas. (From Schneider, A.D., T.A. Howell, A.T.A. Moustafa, S.R. Evett, and W.S. Abou-Zeid. 1998. A simplified weighing lysimeter for monolithic or reconstructed soils. Appl. Eng. Agr. 14:267–273.)

interruption of deep percolation and horizontal flow components, uneven management of lysimeter compared with field soil (Grebet and Cuenca, 1991), and other sources of bias (Ritchie et al., 1996). Other drawbacks include heat flux distortions caused by greatly conductive steel walls (Black et al., 1968; Dugas and Bland, 1991), but minimal for large lysimeters, and high cost, for example, $65,000 (Lourence and Moore, 1991), $80,000 (Marek et al., 1988), and $65,000 (Evett et al., 2009a). All lysimeters have walls, one that retains the soil and is part of the soil container, and another that separates the soil container from the surrounding field soil. A gap between the walls is necessary to allow weighing. The wall-gap surface area is the sum of inside and outside wall horizontal surface areas plus the gap horizontal surface area. Well-designed lysimeters may have a wall-gap surface area as little as 1.5% of the lysimeter soil surface area (Howell and Tolk, 1990).

Schneider et al. (1996) described simplified monolithic weighing lysimeters (Figure 6.32) that were considerably less expensive than, and nearly as accurate as, the monolithic weighing lysimeter described by Evett et al. (2009a) (Figure 6.33). These two designs represent contrasts in mode of operation and each presents some advantages and disadvantages. The design in Figure 6.33 allows access to all sides and the bottom of the lysimeter for installation or repair of sensors and weighing or drainage systems. The data logger that handles all measurements is installed in the underground chamber and typically is subject to only a small diurnal

temperature swing of 1°C, reducing temperature-induced errors in low-level measurements such as load cell transducer bridges and thermocouples. Other equipment that may be installed in the chamber includes a system for TDR measurements of soil water content and bulk electrical conductivity and concurrent measurements of soil temperature, and an automatic vacuum drainage system that continuously monitors drainage rate. The drainage tanks were suspended by load cells from the bottom of the lysimeter tank, allowing measurement of tank mass change without changing the mass of the lysimeter until the tanks are drained (manual but infrequent). The design illustrated in Figure 6.33 overcomes the main disadvantages of the design of Marek et al. (1988), which were the shallow soil depth over the ceiling around the periphery of the chamber and the nearness of the entrance hatch to the lysimeter surface. The shallow soil depth can cause uneven plant growth next to the lysimeter, but this problem can be eliminated with the installation of a drip irrigation system to apply additional water to this area. Access to the lysimeter must be carefully managed to avoid damage to the crop.

Figure 6.32 shows a weighing lysimeter design that minimizes disturbance to the field during both installation and operation. The monolith was collected a short distance away, and the outer box was installed in a square hole that disturbed only a 15 cm perimeter of soil outside the lysimeter. Because there is no access to the sides or bottom of the lysimeter, there is no reason for personnel to visit the lysimeter area except for crop management and the occasional manual drainage accomplished with a vacuum pump and collection bottle. Disadvantages of this design are considerable, and include the lack of continuous drainage data, the fact that manual drainage may not be timely or complete, and the fact that the weighing system is impossible to repair without disassembling the entire lysimeter, which can be costly and time consuming (sometimes months; e.g., Schneider et al., 1998; Marek et al., 2006). This lower cost, direct weighing lysimeter built with no access below the surface at Bushland, Texas (Howell et al., 2000), experienced a weighing system failure due to lightning that required removal of the soil container and scale, which took many weeks, was costly, and disrupted an entire measurement season. A scale failure in a similar lysimeter at Uvalde, Texas, caused Marek et al. (2006) to point out that this "closed" type of design has the potential to result in costly repairs and lengthy loss of data when scales fail. In addition, the remote location of the data logger for the "closed" design can cause problems of electrical interference or signal degradation. The long cable lengths to the external data logger used with the lysimeter in Figure 6.32, and the large diurnal temperature swing to which cables and data logger were exposed, both caused a six-wire bridge to be needed to reduce errors due to temperature-induced resistance changes when reading the platform scale load cells. By contrast, the location of the data logger inside the lysimeter chamber in Figure 6.33 results in diurnal temperature variations being <1°C, allowing a four-wire bridge to be used for reading the weighing system load cell. Measurement precision with the lever beam scale in Figure 6.33 is 0.06 mm, while that with the platform scale in Figure 6.32 is 0.1 mm.
FIGURE 6.33 Cross-sectional view of the large weighing lysimeter at Dayr Alla in the Jordan Valley, Jordan. (From Evett, S.R., N.T. Mazahrih, M.A. Jitan, M.H. Sawalha, P.D. Colaizzi, and J.E. Ayars. 2009a. A weighing lysimeter for crop water use determination in the Jordan Valley, Jordan. Trans. ASABE 52:155–169.)

Weighing lysimeters measure mass change over a given time. If mass is measured in kilograms, then dividing the mass change by the surface area in meter squares of the lysimeter will give the change in water storage, ΔS, of the lysimeter as an equivalent depth of water in millimeter, with only slight inaccuracy due to the density of water not being quite equal to $1\,Mg\,m^{-3}$. If evaporation from bare soil is being measured, then the surface area of the soil within the lysimeter should be used in the calculation. However, if a closed crop canopy is present, then the surface area to be used should be representative of the canopy surface that is supported by the lysimeter. This may be equal to the sum of the lysimeter soil surface area plus one half of the wall-gap surface area, depending on the lysimeter design and crop planting pattern.

If only daily ET values are needed, then ΔS is computed from the 24 h change in lysimeter mass, usually midnight to midnight. Some averaging of readings around midnight may be needed to smooth out noise. The daily ET is computed by summing ΔS with any precipitation or drainage. Data from a continuously weighing lysimeter may be presented as a time sequence of mass (or depth of water storage) referenced to an arbitrary zero (Figure 6.34). Irrigation or precipitation events often will appear as obvious increases in storage (Figure 6.34), and drainage events will show up as decreases in storage. Adjusting the sequential record of storage amount by subtracting the rainfall or irrigation depth, and adding the depth of drainage water, at the time that these occurred, will remove these changes in storage, and is equivalent

to the operations defined by the $+P$ and $+F$ in Equation 6.98; resulting in the monotonically decreasing storage shown in Figure 6.35. Taking the first derivative of the adjusted storage with respect to time gives the adjusted ΔS rate, and thus ET rate (Figure 6.36) (R assumed to be zero). In order to compute ET rates on the same time interval as lysimeter mass measurements are made, we must have concurrent measurements of irrigation, precipitation, and drainage on the same or a finer recording interval.

Weighing lysimeters are subject to wind loading, more so when the soil surface is bare, as evidenced by Figure 6.37. In windy
FIGURE 6.34 Unadjusted weighing lysimeter storage for winter wheat at Bushland, Texas, showing storage increases due to two irrigations.
FIGURE 6.35 Lysimeter storage values from Figure 6.34 adjusted by subtracting irrigation amounts.
FIGURE 6.36 ET rate calculated by taking the negative of the first derivative of adjusted storage from Figure 6.35. The negative ET rates shown for some nights are caused by dew formation.

regions, it may be necessary to smooth the data to remove noise when calculating the ET rate. Gorry (1990), following Savitsky and Golay (1964), described a method for general least squares smoothing that allowed application of different levels of smoothing to both the raw data and their first derivative. Application of this method to post-processing of data is preferable to real-time smoothing that may eliminate detail in the data. With post-processing, we can apply only the amount of smoothing needed to reduce noise to acceptable levels. A computer program to apply Savitsky–Golay smoothing is available (http://www.cprl.ars.usda.gov/programs/).

Microlysimeters are lysimeters small enough to be installed and removed by hand for weighing daily or more often. They have been used to measure the water use of short grass, but lack the soil depth needed for soil water redistribution and drainage that would reproduce the soil profile water content in the adjacent field over the long term. They can give good precision but are sensitive to spatial variability of soil water characteristics, soil profile water content distribution, and surface condition. Lascano and Hatfield (1992) showed that 182 microlysimeters were required to measure field average E with precision of 0.1 mm day^{-1} at a 90% confidence level when their soil was wet but only 39 when dry. This was due to the greater variability of E for wet soil. For a precision of 0.5 mm day^{-1}, only seven microlysimeters were required for any soil wetness. To avoid heat conduction to and from the surface, microlysimeter walls should be made of low thermal conductivity materials such as plastic; and, to avoid trapping heat at the bottom of the microlysimeter, the bottom end cap should be made of a thermally conductive material such as metal (Evett et al., 1995). Plastic pipe makes good microlysimeters. Typical dimensions are 7.6 or 10 cm in diameter and from 10 to 40 cm in height. Beveling the bottom end eases insertion into the soil. Typical practice is to insert the microlysimeter vertically until its top is level with the soil surface; then dig it out, or rotate it to shear the soil at the bottom, and pull it out. After capping the bottom with a water-tight seal, it is weighed before reinsertion into the original or a new hole; sometimes lined with a material (e.g., plastic sheet or bag) to prevent sticking of the soil to the microlysimeter outside surface. After a period of time, the microlysimeter is reweighed and the difference in initial and final weights is the evaporative loss. Short microlysimeters should be replaced daily, as the water supply is soon used up to the point that the soil inside the lysimeter is no longer at the same water content as the soil outside, biasing the measured E. In a study of spatial variability of evaporation from bare soil, Evett et al. (1995) used 30 cm high microlysimeters to avoid daily replacement so that the spatial relationship would not be changed. They showed that for their clay loam soil the 30 cm height was adequate for 9 days. If plant roots are present, it is recommended to replace microlysimeters daily to lessen errors associated with root water uptake that occurs elsewhere in the field but not in the microlysimeters.

Alternatives to weighing lysimetry include soil water measurement methods for assessing ΔS for a soil profile of given depth over a given time. In this case, the soil volume of interest is

unbounded below the surface and F is, strictly speaking, uncontrolled. Measurements of soil water content can give the change in soil water stored in a profile of given depth with good accuracy; and can give good values for E if water flux across the bottom of the profile is known or can be closely estimated. Baker and Spaans (1994) described a microlysimeter with TDR probe installed vertically to measure the water content. Comparison of E calculated from the change in storage determined with TDR closely matched the E measured by weighing the microlysimeter. Young et al. (1997) showed that a single 800 mm long probe installed vertically from the surface could account for 96% of ET from weighing lysimeters irrigated on a 6 day interval; but standard error for the probe was about four times larger than that for the lysimeter (0.46 and 0.07 mm, respectively). In a container study with a sorghum plant, Wraith and Baker (1991) showed that a TDR system could measure ET with good resolution and provide measurements of change in storage on a 15 min interval that compared very well with those measured by an electronic scale. Despite the good laboratory performance of TDR for soil E and ET determinations, outdoor installations are limited by the depth to which TDR probes can be installed without disturbing the soil profile unduly, and the diurnal and seasonal temperature effects on TDR derived water contents, which can bias E and ET determinations.

Evett et al. (1993) showed that change in storage in the upper 35 cm of the profile under winter wheat could be accurately tracked with horizontally placed TDR probes, with an average of 88% of daily ΔS occurring in the upper 30 cm. But, E estimates were incorrect (compared with a weighing lysimeter) when flux across the 35 cm lower boundary occurred. However, combination of the TDR system with neutron moisture meter (NMM) measurements of deeper soil moisture allowed measurement of E to within 0.7 mm of lysimeter measured ET over a 16 day period; five times better than the accuracy achieved using only NMM measurements.

Figure 6.38 shows the soil water storage (referenced to arbitrary zero) as measured for winter wheat by weighing lysimeter and two TDR arrays. Each TDR array consisted of seven probes inserted horizontally into the side of a pit and the pit backfilled after wheat planting. Probe depths were 2, 4, 6, 10, 15, 20, and 30 cm, and the probes were read every half hour. Rains on days 101, 104, and 106 can be seen as increases in the storage amount. Changes in storage as measured by the two systems were nearly identical in the 7 day period shown (Figure 6.39); and ET amounts were closely similar (Figure 6.40).

Water balance measurement intervals commonly range between hours and weeks and are usually no smaller than the required period of ET measurement. Measurement of each variable in Equation 6.97 presents its own unique problems. These include measurement errors in determination of lysimeter mass or ΔS, and errors in P and R measurements. Problems of P and R measurement are essentially identical for either weighing lysimetry or soil profile water content methods because the surface area of the control volume can be defined for both methods with a water-tight border, often consisting of a sheet metal square
FIGURE 6.38 Soil water storage in the upper 35 cm of the soil profile, as measured by two TDR probe arrays, compared with storage in a 2.4 m deep weighing lysimeter. Zero reference is arbitrary. Winter wheat, Bushland, Texas, 1992.
FIGURE 6.39 Daily change in storage for the 35 cm and 2.4 m profiles from Figure 6.38.
FIGURE 6.40 Daily ET as calculated from the TDR and weighing lysimeter data shown in Figure 6.38 and assuming $F = 0$.

or rectangle pressed into or partially buried in the soil surface. When the soil volume is unbounded below the surface, as in the soil profile water content method, there are additional errors due to uncontrolled horizontal flow components and deep percolation that are difficult to measure or estimate. Nevertheless, the profile water balance technique is applicable in many situations for which lysimetry is inappropriate or impossible and is, in addition, much less expensive. In many cases, the horizontal flow components may be assumed to sum to zero; and deep percolation may be nil if the soil profile water content measurements are made to sufficient depth (Wright, 1990).

When the NMM alone is used to measure soil water content, the soil water balance method is suitable for periods of several days or more if closure ($F \approx 0$) at the bottom of the measured soil profile can be obtained (Wright, 1990). The NMM has been commonly used (Cuenca, 1988; Wright, 1990) but due to the small changes in water content associated with daily ET, this water balance method has usually been restricted to determination of ET over several-day periods (Carrijo and Cuenca, 1992). Evett et al. (1993) showed that TDR measurements of soil water content near the surface could be coupled with deeper water content measurements by NMM to close the water balance considerably more precisely than with the NMM alone, opening up the prospect for daily ET measurements by this method.

Although several alternatives to the NMM have been introduced, all depending on sensing a change in the soil's electrical properties due to water content changes, none of these has proven useful for ET determinations due to interference from soil temperature, bulk electrical conductivity, and bound water effects on the soil dielectric permittivity, which are particularly important in superactive clay soils but present in nearly all soils (Evett et al., 2008), the limited measurement depth of some of the available sensors (Mazahrih et al., 2008), and the problems with small-scale spatial variability and nonrepresentativeness of readings uncovered by Evett et al. (2009b). The latter authors found that, in the field, the dielectric sensors used in access tubes were less precise than either the NMM or gravimetric sampling. Mazahrih et al. (2008) pointed out several studies in which soil water uptake was substantial to depths >3 m for crops such as corn, cotton, sugar beet, and winter wheat. A soil water sensing system for ET determination must be capable of determining the water content of the entire soil profile from the surface to well below the zone of root water uptake if the control volume is to be closed and ET estimates assured without errors due to deep F.

Surface storage has been ignored in the discussion of soil water balance here, but it not only has a large influence on the amount of water infiltrated from a precipitation or irrigation event, but it is also one of two factors that are the most amenable to human control both on a small and large scale. The other is infiltration rate, a soil property that may be increased by soil tillage over the short term, and decreased by tillage in the long term, and also may be influenced by no-tillage or minimum-tillage practices, by tree plantings and ground covers designed to protect the soil surface from slaking and crusting, and many other practices. Many farming efforts are aimed at increasing surface storage through practices like plowing to roughen the soil surface or furrow diking to create infiltration basins and decrease runoff, to name two. Soil conservation measures such as terraces, contour bunds, etc., are aimed at decreasing runoff or runoff velocity, and thus increasing the opportunity time for infiltration. On the other hand, water harvesting is a practice of increasing runoff by reducing both surface storage and infiltration rate, with the aim of using the runoff water elsewhere. Among the oldest artifacts of human cultivation are water harvesting systems that included the removal of gravel from desert surfaces to improve runoff, terrace systems for guiding and reducing runoff, and in some cases, the combined use of both technologies to concentrate water on an area chosen for cultivation (Shanan and Tadmor, 1979). To the extent that such practices influence infiltration, they will affect the timing, magnitude, and spatial patterns of such energy balance terms as sensible and latent heat fluxes, and the convective heat flux accompanying infiltrating water.

6.3.2 Estimating Flux across the Lower Boundary

One of the great advantages of lysimeters is that they control the soil water flux, F, into and out of the control volume. To date, a reliable soil water flux meter has not been developed, so F must be estimated if it is not controlled. If water flux across the lower boundary of the control volume is vertical, it may sometimes be estimated by measurements (preferably multiple) of soil water potential, h, at different depths separated by distance, Δz, and knowledge of the dependence of hydraulic conductivity, K (m s^{-1}), on soil water potential, the $K(h)$ curve. The potential difference, Δh, coupled with the unit hydraulic gradient for vertical flux, gives the hydraulic head difference, ΔH, driving soil water flux. Averaging the measurements allows estimation of the mean hydraulic conductivity for the soil layer between the measurement depths from the $K(h)$ curve, and thus estimation of the soil water flux, J_w (m s^{-1}), from a finite difference form of Darcy's law

$$J_w = -K\left(\frac{\Delta H}{\Delta z}\right). \tag{6.99}$$

Soil water potential may be measured by tensiometer or other means described in Chapter 3 (or see van Genuchten et al., 1991). Methods of measuring or estimating the $K(h)$ curve may be found in Chapter 4. For fluxes across boundaries too deep for the installation of tensiometers, the soil water content may be measured at two or more depths by the NMM (see Chapter 3) and the soil water potential inferred by inverting the $\theta_v(h)$ relationship, which may be estimated or measured (see Chapter 3 or van Genuchten et al., 1991). Due to the hysteresis of the $\theta_v(h)$ relationship, there is more room for error when basing J_w estimates on θ_v measurements. But, for many cases, the soil water potential

will be in the range where hysteresis is not a large source of error (drier soils), and hydraulic conductivity is not large either. Thus, both the value of J_w and the error in J_w may be small enough for practical use in determinations of ET.

6.3.3 Precipitation and Runoff

An in-depth discussion of precipitation and runoff measurement and modeling is beyond the scope of this chapter. A classic and still valuable reference on field hydrologic measurements is the *Field Manual for Research in Agricultural Hydrology* (Brakensiek et al., 1979). A more up-to-date and extensive reference is the *ASCE Hydrology Handbook*, 2nd edition (ASCE, 1996). Flow measurement in channels is detailed in *Flow Measuring and Regulating Flumes* (Bos et al., 1983). The monograph *Hydrologic Modeling of Small Watersheds* (Hann et al., 1982) included useful chapters on stochastic modeling, precipitation and snowmelt modeling, runoff modeling, etc., and listed some 75 hydrologic models available at that time. For soil water balance measurements, runoff is often controlled with plot borders or edging driven into the ground or included as the above-ground extension of a lysimeter. Steel borders driven into the soil to a depth of 20 cm will suffice in many situations. Sixteen gauge-galvanized steel in rolls 30 cm wide is useful for this and can be reinforced by rolling over one edge. If runoff must be measured, this can be done with flumes such as the H-flume and recording station shown in Figure 6.41.

Precipitation varies so much from location to location that it is rarely useful to attempt estimating it. Measurement methods include standard U.S. Weather Bureau rain gauges read manually, various tipping bucket rain gauges, heated gauges to capture snow fall (e.g., Qualimetrics model 6021, Sacramento, CA), snow depth stations, etc. A rain gauge should be located as close to the surface as possible and be surrounded by a wind shield to avoid catch loss associated with wind flow over the gauge (Figure 6.42). A standard for the capture area or throat of a rain gauge is that it should be 20 cm in diameter because smaller throats lead to more variability in amount captured. Various designs of tipping bucket rain gauge have become

FIGURE 6.41 H-flume and recorder (in white box) for measuring runoff rate from a graded bench terrace at Bushland, Texas. Note dike diverting flow from uphill flume.

FIGURE 6.42 Wind shield installed around a heated, tipping bucket rain gauge.

standard equipment on field weather stations. These are capable of providing precipitation data needed to solve the soil water balance for short intervals. Two problems are sometimes associated with tipping bucket type gauges. First, most of these devices count the tips using a Hall-effect sensor for detecting the magnetic field of a magnet attached to the tipping bucket; and the sensing system is sometimes susceptible to interference from sources of electromagnetic noise such as vehicle ignition systems, generators, lightning strikes, etc. Second, tipping bucket gauges do not keep up with very large rainfall rates. In regions with predominantly small rainfall events, a third error due to the water left in the tipping bucket at the end of precipitation may result in significant accumulative errors in seasonal precipitation. At Bushland, Texas, we have observed tipping bucket errors of 10%–15% for totals of rainfall from high intensity convective thunderstorms compared with amounts collected in standard rain gauges and sensed by weighing lysimeters. If accuracy is very important, then a tipping bucket gauge should be supplemented with a standard gauge that captures and stores all the rainfall. For solving the soil water balance, experience shows that the rain gauge(s) should be placed directly adjacent to the location of ΔS measurement. Separation of even 100 m can lead to large errors due to the spatial variability of precipitation.

For studies and operations at scales larger than small field size, there are now precipitation estimates from Doppler radar-based systems that offer calibrated rainfall data on a 24 h basis (Figure 6.43; see also Legates et al., 1996; Vieux and Farajalla, 1996). Although Figure 6.43 shows large grid sizes and only 16 levels of precipitation, grid sizes of 4 km on a side, with 256 levels of rainfall, are available. Data for these maps are generated by the WSR-88D radar system, usually known as the NEXRAD weather radar system, in widespread use in the United States. The Center for Computational Geosciences at the University of Oklahoma has developed a radar-based precipitation interface (RPI) for the radar data to generate the maps. Radar data are used from two or more stations and calibrated against rain gauge measurements available from, for example, the Oklahoma MESONET system of weather stations.

Solute Transport

Feike J. Leij

Long Beach*

Antonella Sciortino
*California State University,
Long Beach*

7.1 Introduction

Soil scientists and agricultural engineers have traditionally been interested in the behavior and effectiveness of agricultural chemicals (fertilizers and pesticides) applied to soils for enhancing crop growth, as well as in the effect of salts and other dissolved substances in the soil profile on plant growth. More recently, concern for the quality of the vadose zone and possible contamination of groundwater has provided a major impetus for studying solute transport in soils.

The movement and fate of solutes in the subsurface are affected by a large number of physical, chemical, and microbiological processes requiring a broad array of mathematical and physical sciences to study and describe solute transport. A range of experimental and mathematical procedures may be employed to quantify transport in soils. Transport of a dissolved substance (solute) depends on the magnitude and direction of the solvent (water) flux; considerable experimental and numerical effort may be needed to determine the transient flow regime in unsaturated soils. Furthermore, the determination of solute concentrations is not always straightforward, particularly if the solute is involved in partitioning between different phases or subject to transformations. Solute transport in porous media is studied in many scientific disciplines such as soil science, civil and environmental engineering, geology, and chemistry. A vast body of literature exists on the subject, and this chapter provides a somewhat subjective introductory treatment of the solute transport in soils. First, the standard transport mechanisms pertaining to the fundamental advection–dispersion equation (ADE) will be introduced in Section 7.2. This equation, also known as the convection–dispersion equation, is most often used to model solute transport in porous media. The movement of a solute that undergoes adsorption by the soil requires modifications of the ADE, particularly if several solute species are present that may participate in a number of different reactions. Section 7.3 is devoted to analytical and numerical methods for quantifying solute concentrations as a function of time and space. The traditional advection–dispersion concept is not always adequate to describe solute transport in field soils. Section 7.4 describes the stream tube model as an example of an alternative transport model that may be better suited to model transport in real-world situations. Finally, Section 7.5 deals with the dissolution of nonaqueous phase contaminants into the aqueous phase.

7.2 Advection–Dispersion Equation

Consider the transport of a chemical species in a three-phase soil–air–water system, and assume that the chemical species (the solute) is completely miscible with water (the solvent). At the macroscopic level and for one-dimensional flow, the mass balance equation for a solute species subject to arbitrary reactions is given as

$$\frac{\partial(\theta C)}{\partial t} = -\frac{\partial J_s}{\partial x} + \theta R_s,$$
(7.1)

where

  θ is the volumetric water content ($L^3 L^{-3}$)

  C is the solute concentration expressed as solute mass-per-solvent volume ($M L^{-3}$)

  t is time (T)

  x is position (L)

  J_s is the solute flux expressed in solute mass-per-cross-sectional area of soil-per-unit time ($M L^{-2} T^{-1}$)

  R_s denotes arbitrary solute sinks (<0) or sources (>0) due to zero- or higher-order rate processes in the aqueous phase or transfer to another phase ($M L^{-3} T^{-1}$)

For a conservative or nonreactive solute, R_s equals 0. Similar equations may be derived for multidimensional flow and transport. The solute flux is composed of an advective and a dispersive component according to

$$J_s = J_w C + J_D, \tag{7.2}$$

where

  J_w is the volumetric water flux ($L T^{-1}$), that is, the Darcian velocity expressed as volume of water-per-cross-sectional area of soil-per-unit time

  J_D is a solute flux to quantify transport caused by a gradient in the solute concentration ($M L^{-2} T^{-1}$), also per unit area of soil

7.2.1 Solute Spreading

The movement of a solute with flowing water, described by the solute flux ($J_w C$), is referred to as advection or convection. Because dissolved substances move in a passive fashion, advective transport can be readily quantified when the solvent flux (J_w) is known. The water flux is generally a function of time and position. However, for transport in laboratory soil columns, it is often constant while simplifications may also be possible for field studies.

Even if the macroscopic water flux is known or can be measured, the velocity at smaller pore scales is not easily determined. Variations in the microscopic velocity will lead to unequal solute movement in the direction of flow. This movement is quantified by means of the dispersive solute flux. If, during steady water flow, the solute concentration of the solution at the inlet of a water-saturated soil column is changed abruptly at time $t = 0$, the observed breakthrough of a solute at the column outlet at times $t > 0$ will not exhibit an equivalent abrupt change (Nielsen and Biggar, 1961). The solute concentration will change more gradually with time as a result of (hydrodynamic) dispersion, which quantifies the effects of both mechanical dispersion and diffusion. Molecular diffusion and mechanical dispersion will be discussed first for "free" solutions and then for soil solutions.

7.2.1.1 Diffusion

Molecular or ionic diffusion is an important mechanism for solute transport in soils in directions where there is little or no water flow. A net transfer of molecules of a solute species usually occurs from regions with higher to lower concentrations as

the result of diffusion as described by Fick's first law. Diffusive transport in the free or bulk solution is given by

$$J_{dif} = -D_o \frac{\partial C}{\partial x}, \tag{7.3}$$

where

  J_{dif} is the one-dimensional mass flux ($M L^2 T^{-1}$)

  D_o is the coefficient of molecular diffusion for a free or bulk solution ($L^2 T^{-1}$)

Many publications exist that provide data on D_o (Kemper, 1986; Lide, 1995).

The experimentally observed proportionality between J_{dif} and the concentration gradient can be described at the molecular or ionic level with a balance of forces. The driving force for particle movement from higher to lower concentrations is the gradient in the chemical potential. For mixtures with ideal behavior, the chemical potential can be expressed in terms of its mole fraction. For solutions with nonideal mixing behavior, the activity coefficient of the solute needs to be determined. Ionic activity coefficients can be estimated with the extended Debye–Hückel equation or the Davies extension for solutions up to 0.5 M. Activity coefficients for a greater concentration range up to 16 M can be estimated with the Pitzer virial equations (Pitzer, 1979; Harvie and Weare, 1980). Codiffusion or counterdiffusion occurs in systems with multiple ion species. Diffusion rates for individual species as predicted solely by Fick's model would violate the electroneutrality principle. The ionic diffusion flux consists then of a term for ordinary Fickian diffusion and a term accounting for electric transference of ions. The corresponding diffusion coefficient is related to the ionic mobility using the Nernst–Planck equation (Helfferich, 1962).

To characterize diffusion in soils, the coefficient for diffusion of a substance in a free solution is typically adjusted with terms accounting for a reduced solution phase (a smaller cross-sectional area available for diffusion) and an increased path length. A general treatment of diffusion in soils can be found in Olsen and Kemper (1968) and Nye (1979). The macroscopic diffusive flux per unit area of soil can be written as

$$J_{dif} = -\theta D_{dif} \frac{\partial C}{\partial x}, \tag{7.4}$$

with D_{dif} as the coefficient of molecular or ionic diffusion for the liquid phase of the soil. Diffusion coefficients for the soil liquid and a free liquid are related by (Epstein, 1989)

$$D_{dif} = \frac{D_o}{(L_{dif}/L)^2} \equiv \frac{D_o}{\tau^2} \equiv D_o \tau_o, \tag{7.5}$$

where

  L_{dif} and L are the actual and the shortest path lengths for diffusion (L)

  $\tau = L_{dif}/L$ is known as the tortuosity

  τ^2 is the tortuosity factor, while $\tau_a = (L/L_{dif})^2$ is often designated as an apparent tortuosity factor

The tortuosity L_{dif}/L is squared in Equation 7.5 because the concentration gradient along the streamline diminishes and the travel distance increases in the soil solution compared with diffusion along a straight path with length L in a free solution (Olsen and Kemper, 1968). It should be noted that the terms tortuosity and tortuosity factor have not been used consistently in the literature. Furthermore, some authors include the water content in their definition of tortuosity (Dykhuizen and Casey, 1989) or solute adsorption (retardation) in the expression for either τ or D_{dif} (Nye, 1979; Robin et al., 1987).

For unsaturated conditions, it is convenient to quantify the dependency of the diffusion coefficient on water content. Assuming that the tortuosity affects diffusion in the liquid phase in the same way as in the gaseous phase, the tortuosity term previously derived for gaseous diffusion in soils by Millington (1959) and Millington and Quirk (1961) can be adapted to describe aqueous diffusion in variably saturated soils. The following expressions then result:

$$D_{dif} = \frac{\theta^{10/3}}{\varepsilon^2} D_o, \tag{7.6a}$$

$$D_{dif} = \frac{\theta^2}{\varepsilon^{2/3}} D_o, \tag{7.6b}$$

where ε is the soil porosity ($L^3 L^{-3}$). An equivalent of the first expression, using a volumetric air content instead of θ, has been used frequently to describe gaseous diffusion in soils although Jin and Jury (1996) reported that the lesser known second version provided a better description.

Diffusion coefficients in soil systems are usually determined by mathematically analyzing solute concentration profiles in the soil as a function of time or position. Results and procedures for diffusion in soils have been summarized by Flury and Gimmi (2002). van Rees et al. (1991) measured diffusivities by allowing diffusion from a spiked solution or soil sample into a solute-free medium. Typically, two blocks of soil with different concentrations are brought together at time $t = 0$ (Kemper, 1986; Oscarson et al., 1992). After sufficient time has elapsed for solute diffusion to occur from the block with the higher to the lower concentration, the joined soil blocks are sectioned. The solute concentration of each section is determined, for example, by using extraction, centrifugation, and chemical analysis of the supernatant liquid. This approach yields a concentration profile versus distance from which the diffusion coefficient may be estimated using an appropriate analytical solution of the governing solute diffusion equation. Consider the diffusion equation,

$$\frac{\partial C}{\partial t} = D_{dif} \frac{\partial^2 C}{\partial x^2}, \tag{7.7}$$

subject to the initial condition,

$$C(x,0) = \begin{cases} C_o & -\infty < x < 0 \\ C_i & 0 < x < \infty \end{cases}, \tag{7.8}$$

and the approximate boundary conditions

$$C(-\infty,t) = C_o, \quad C(\infty,t) = C_i. \tag{7.9}$$

The solution for this problem is given by (Crank, 1975)

$$C(x,t) = C_i + 0.5(C_o - C_i)\operatorname{erfc}\left(\frac{x}{\sqrt{4D_{dif}t}}\right), \tag{7.10}$$

where erfc is the complementary error function (Gautschi, 1964).

7.2.1.2 Dispersion

Local variations in water flow in a porous medium will lead to mechanical dispersion. Several mechanisms that are commonly used to contribute to mechanical dispersion are illustrated with hypothetical tracer particles in Figure 7.1. Dispersion may occur because of (a) the development of a velocity profile within an individual pore such that the highest velocity occurs in the center of the pore and presumably little or no flow at the pore walls; (b) different mean flow velocities in pores of different sizes; (c) the mean water flow direction in the porous medium being different from the actual streamlines within individual pores, which differ in shape, size, and orientation; and (d) solute particles converging to or diverging from the same pore. All these processes contribute to solute spreading, in which initially steep concentration fronts become smoother during movement along the main flow direction.

Taylor (1953) analyzes dispersion of a solute injected in a cylindrical tube with laminar flow; this study is often used to elucidate dispersion in porous media. For laminar flow in a cylindrical tube filled with water, the parabolic velocity profile is

$$q(r) = q_o\left(1 - \frac{r^2}{r_o^2}\right), \tag{7.11}$$

where

q_o is the maximum velocity at the center of the tube ($L\ T^{-1}$)
r is the radial distance from the axis (L)
r_o is the tube radius (L)

The mean velocity over a cross section of the tube equals $q_o/2$. If a solute is injected in the tube, the velocity profile tends to stretch its concentration profile while diffusion will mitigate the large (transverse) concentration gradients caused by the velocity distribution. Taylor skillfully analyzed the governing two-dimensional transport problem. He obtained the following dispersion coefficient assuming proportionality between the longitudinal solute flux and the concentration gradient (i.e., Fick's law is applicable):

$$D_{dis} = \frac{r_o^2 v_o^2}{192 D_o}. \tag{7.12}$$
FIGURE 7.1   Schematic concepts contributing to mechanical dispersion.

Note that D_{dis} (L^2 T^{-1}) is inversely proportional to the coefficient of molecular diffusion D_o after sufficient time has elapsed for equilibrium to be established. The results by Taylor were later derived for more general conditions by Aris (1956) using moment analysis.

The Taylor–Aris model has been widely applied to describe dispersion in porous media. It was adapted early on in soil physics by Nielsen and Biggar (1962). Research to further elucidate dispersion phenomena in porous media has continued along the lines of the original theory (e.g., Gupta and Bhattacharya, 1983). At the early stage, dispersion in soils cannot be described as a Fickian process, and other models may need to be employed (Jury and Roth, 1990).

The one-dimensional solute flux due to mechanical dispersion in a uniform isotropic soil may be approximated using Fick's law:

$$J_{dis} = -\theta D_{dis} \frac{\partial C}{\partial x}, \tag{7.13}$$

where J_{dis} is the dispersive solute flux (M L^{-2} T^{-1}). Because of the similarity between Equations 7.4 and 7.13, solute spreading during transport in soils is typically described with a single coefficient of hydrodynamic dispersion, that is, $D = D_{dis} + D_{dif}$. As is often noted, this is done for convenience in spite of the conceptual differences between the diffusion and dispersion mechanisms (Scheidegger, 1974). The practice is consistent with results from laboratory and field experiments, which do not permit a distinction between mechanical dispersion and molecular diffusion. The hydrodynamic dispersive flux (J_D) (Equation 7.2) consists of contributions from molecular diffusion (Equation 7.4) and mechanical dispersion (Equation 7.13):

$$J_D = J_{dif} + J_{dis}. \tag{7.14}$$

Since diffusion is independent of flow, the contribution of diffusion to hydrodynamic dispersion diminishes if the soil water flow

rate increases. Hydrodynamic dispersion is often simply referred to as dispersion, as will be done in the remainder of this chapter.

The effects of dispersion can be illustrated with a hypothetical laboratory experiment in which water and a dissolved tracer are applied to an initially tracer-free, uniformly packed soil column of length $L = 1$ m (Figure 7.2a). The column is subjected to steady-state water flow with uniform water content. The average pore water or interstitial velocity $v = 0.5$ m day^{-1}. Note that v is the actual travel-time velocity, which is given per unit area of fluid. It is determined by the ratio of the Darcian water flux density (J_w) and the volumetric water content (θ), where J_w is defined per unit area of (bulk) soil. There is a step change in solute concentration at the inlet (Figure 7.2b), and the solute front becomes smoother because of solute spreading during passage of the soil column (Figure 7.2c). A smooth effluent curve can be monitored at the column exit as shown in Figure 7.2d. In the absence of diffusion and dispersion ($D = 0$), the front of a perfectly inert tracer will travel as a square wave through the column (a process often called piston flow) to reach the bottom of the column at time $t = L/v$. For piston flow, a conservative tracer reaches the column exit exactly after one pore volume of tracer solution has been injected (or collected at the column exit). Pore volume is defined as the volume of water stored in that column.

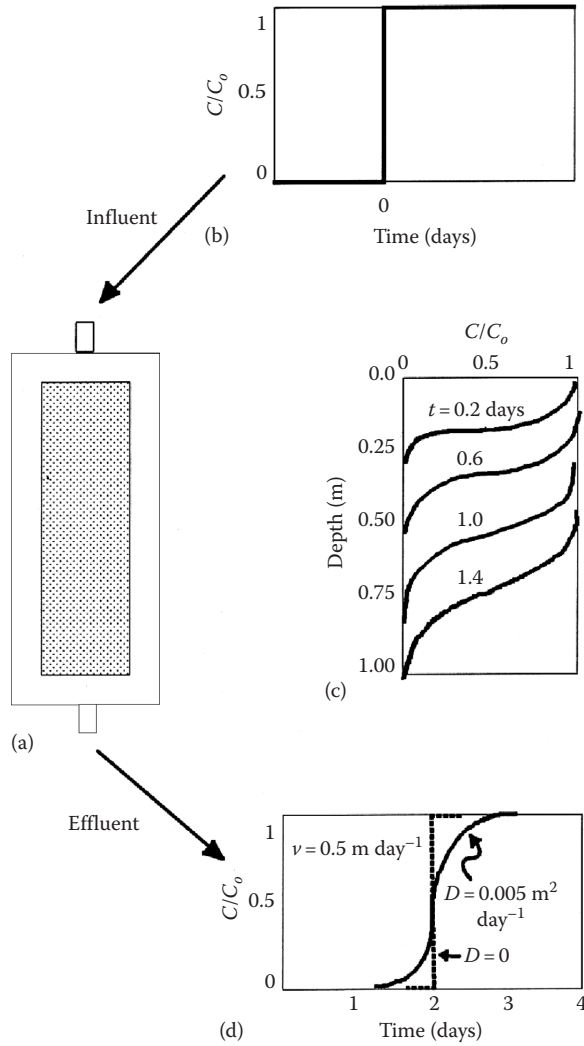
The degree of spreading is usually related to the solute travel time, although some constraints do exist on the amount of spreading. Dispersion, as sketched in Figure 7.1a, is limited because of transverse molecular diffusion, which causes solutes to move from the center of a tube to areas near the pore walls, or vice versa, in response to local concentration gradients. Such transverse diffusion counteracts spreading caused by variations in the longitudinal flow velocity. Dispersion is also limited since capillaries in a porous medium generally are not independent cylindrical tubes, but branch and join or rejoin each other at distances characteristic of the pore or particle size distribution of the medium. This branching and rejoining promote lateral mixing of solutes from different pores as sketched in Figure 7.1d.


FIGURE 7.2 Hypothetical laboratory tracer experiment: (a) column of soil, (b) influent curve, (c) concentration distributions inside the column, and (d) breakthrough curves with and without dispersion. (Modified after van Genuchten, M.Th. 1988. Solute transport, p. 360–362. *In* S.P. Parker (ed.) McGraw-Hill yearbook of science and technology. McGraw-Hill Book Co., New York.)

Three-dimensional dispersion is quantified with a dispersion tensor. The components of the symmetric dispersion tensor for an isotropic soil are given as (Bear and Verruijt, 1987)

$$D_{ij} = \delta_{ij}\alpha_T \, |\vec{v}| + \frac{(\alpha_L + \alpha_T)v_i v_j}{|\vec{v}|}, \qquad (7.15)$$

where
  $|\vec{v}|$ denotes the magnitude of the pore water velocity with v_i as the ith component (L T^{-1})
  δ_{ij} is the Kronecker delta ($\delta_{ij} = 1$, if $i = j$ and $\delta_{ij} = 0$, if $i \neq j$)
  α_L and α_T are, respectively, the longitudinal and transverse dispersivity (L)

For a one-dimensional system, Equation 7.15 reduces to $D_{dis} = \alpha_L|v|$. Mechanical dispersion, as sketched in an idealized fashion in Figure 7.1a, can be reversed by changing the flow direction to make a smooth front steep again. In soils, however, dispersion is not reversible since mixing erases antecedent concentration distributions, as illustrated in Figure 7.1d. Absolute values are, therefore, used for v in Equation 7.15. In case of uniform water flow parallel to the x-axis of a Cartesian coordinate system, only the following three main components of Equation 7.15 need to be considered:

$$D_{xx} = \alpha_L v, \quad D_{yy} = \alpha_T v, \quad D_{zz} = \alpha_T v, \qquad (7.16)$$

where
  D_{xx} is the coefficient of longitudinal (mechanical) dispersion
  D_{yy} and D_{zz} are the coefficients of transverse dispersion

Dispersion coefficients may be determined by fitting a mathematical solution to observed concentration (Toride et al., 1995). Additional procedures to determine dispersion coefficients are given by Fried and Combarnous (1971) and van Genuchten and Wierenga (1986). Values of the longitudinal dispersivity (α_L) for laboratory experiments typically vary between 0.1 and 10 cm with 6–20 times smaller values for α_T (Klotz et al., 1980). Dispersivities for field soils are generally much higher. Gelhar et al. (1992) reviewed published field-scale dispersivities determined in aquifer materials that are typically one or two orders of magnitudes larger, even more so for relatively large experimental scales.

7.2.2 Advection–Dispersion Equation

The expressions for the advective and dispersive solute fluxes can be substituted in mass balance Equation 7.1. The one-dimensional ADE for solute transport in a homogeneous soil becomes

$$\frac{\partial(\theta C)}{\partial t} = -\frac{\partial}{\partial x}\left(J_w C - \theta D\frac{\partial C}{\partial x}\right) + \theta R_s. \qquad (7.17)$$

In the case where the water content is invariant with time and space, the ADE may be simplified to ($v = J_w/\theta$),

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x} + R_s. \qquad (7.18)$$

This is a parabolic differential equation similar to the diffusion equation. To complete the mathematical formulation of the transport, several concentration types and mathematical conditions will be reviewed in Section 7.3.1.

A variety of solute source or sink terms may be substituted for R_s. The most common source/sink term is due to adsorption/desorption and ion exchange stemming from chemical and physical interactions between the solute and the soil solid phase.

Many other processes such as radioactive decay, aerobic and anaerobic transformations, volatilization, photolysis, precipitation/dissolution, reduction/oxidation, and complexation may also affect the solute concentration. A further refinement of the transport model is necessary in the case of nonuniform interactions between the solute and the soil, or if there is adsorption on moving particles and colloids. In the following, only interactions at the solid–liquid interface will be considered.

7.2.3 Adsorption

Dissolved substances in the liquid phase can interact with several soil constituents such as primary minerals, oxides, and inorganic or organic colloids. Dissolved ions in the soil solution counterbalance the surface charge of soil particles caused by isomorphous substitution of one element for another in the crystal lattice of clay minerals, by the presence of hydronium or hydroxyl ions at the solid surface, or other mechanisms. The net surface charge of an assemblage of soil particles produces an electric field that affects the distribution of cations and anions within water films surrounding the soil particles.

Adsorption of solute (adsorbate) by the soil (adsorbent) is an important phenomenon affecting the fate and movement of solutes. The ADE for one-dimensional transport of an adsorbed solute may be written as

$$\frac{\partial C}{\partial t} + \frac{\rho_b}{\theta}\frac{\partial S}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x}, \tag{7.19}$$

where S is the adsorbed concentration, defined as mass of solute per mass of dry soil ($M\ M^{-1}$). The above equation can be expressed in terms of one dependent variable by assuming a suitable relationship between the adsorbed and liquid concentrations. This is typically done with a simple adsorption isotherm to quantify the adsorbed concentration as a function of the liquid concentration at a constant temperature. In addition to temperature, the adsorption isotherm is generally also affected by the solution composition, total concentration, the pH of the bulk solution, and sometimes the method used for measuring the isotherm. A mathematically pertinent distinction is often made between linear and nonlinear adsorption. Although most adsorption isotherms are nonlinear, the adsorption process may often be assumed linear for low solute concentrations or narrow concentration ranges.

7.2.3.1 Linear Adsorption

Consider the general case of nonequilibrium adsorption, where a change in C is accompanied by a delayed change in S. The adsorption rate can be described assuming first-order kinetics:

$$\frac{\partial S}{\partial t} = kh(C,S), \tag{7.20}$$

where
  k is a rate parameter (T^{-1})
  h is a function to quantify how far the adsorption or desorption process is removed from equilibrium

A single-valued isotherm for equilibrium adsorption $\Gamma(C)$ is used to define $h(C, S)$ according to

$$h(C,S) = \Gamma(C) - S. \tag{7.21}$$

For equilibrium adsorption $k \to \infty$, and hence $h(C, S) \to 0$, which implies that $S = \Gamma(X)$. For a linear adsorption isotherm, the relation between Γ and C can simply be given as

$$\Gamma = K_d C, \tag{7.22}$$

where K_d is a partition coefficient, often referred to as the distribution coefficient, expressed in volume of solvent per mass of soil ($L^3\ M^{-1}$). For $S = \Gamma$, substitution of Equation 7.22 into Equation 7.19 leads to the following ADE commonly used to describe transport of a solute that undergoes linear equilibrium exchange:

$$R\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x}, \tag{7.23}$$

in which the retardation factor R is given by

$$R = 1 + \frac{\rho_b}{\theta}K_d, \tag{7.24}$$

with ρ_b as soil bulk density. The advective and dispersive fluxes are reduced by a factor R as a result of adsorption. The movement of the solute is said to be retarded with respect to the average solvent movement. If there is no interaction between the solute and the soil ($K_d = 0$), the value for R is equal to unity. The value for R may be calculated from K_d as obtained from chemical analyses of the solution and adsorbed phases. Frequently, R is obtained by optimizing a mathematical solution to observed concentrations. For step application of a solute to a soil column (cf. Figure 7.2), the net solute flux into the column should be equal to the change in the amount of solute in the soil column. The following mass balance can hence be formulated to estimate R:

$$v\big[g(t) - C_e\big] = R\int_0^L \big[C(x,t) - f(x)\big]\,dx, \tag{7.25}$$

where
  C_e is the effluent concentration
  $f(x)$ and $g(t)$ are the initial and influent concentrations, respectively

The effects of linear adsorption on solute transport in a homogeneous soil profile are shown in Figure 7.3. Analytically predicted solution and adsorbed concentrations are plotted 4 days after the start of a 1-day application of influent with a unit solute concentration (units may be selected arbitrarily, e.g., g m^{-3}) to an initially solute-free soil profile subject to steady saturated water flow. Other parameters for this example are $J_w = 10$ cm day^{-1}, $\theta = 0.40$ cm^3 cm^{-3}, and $D = 62.5$ cm^2 day^{-1}. The pore water velocity ($v = J_w/\theta$) is hence 25 cm day^{-1} and $\alpha_L = 2.5$ cm. Solute distributions are plotted for three values of the retardation factor, R (Figure 7.3).
FIGURE 7.3 Effect of adsorption, as accounted for by the retardation factor R, on (a) solution (C) and (b) adsorbed (S) concentration distributions in a homogeneous soil profile.

When R is increased from 1.0 to 2.0, the apparent solute velocity (v/R) is reduced by one-half (Figure 7.3a), causing a shallower penetration of the solute pulse into the profile. At the same time, the area under the curve in Figure 7.3a is also reduced by one-half. When $R = 4$, the apparent solute velocity and the area under the curve are again reduced by half. The distribution for the adsorbed concentration S, which may be expressed as mg kg^{-1} soil, increases from 0 (no adsorption) when $R = 1$ to a maximum when $R = 4$ are similar (Figure 7.3b). Assuming a soil bulk density (ρ_b) of 1.25 g cm^{-3} and the same water content as before ($\theta = 0.40$ cm^3 cm^{-3}), one may calculate, using Equation 7.24, that the distribution coefficient $K_d = 0$, 0.32, and 0.96 cm^3 g^{-1} for $R = 1$, 2, and 4, respectively.

Anion exclusion occurs when negatively charged surfaces of clays and ionizable organic matter are present; anions are repelled from such surfaces and accumulate in the center of pores. Because water flow velocities are 0 at pore walls and maximum in the center of pores (Figure 7.1a), the average anion movement will be faster than the average water movement. Many displacement experiments also suggest faster anion than water movement simply because the apparent displacement volume is smaller for anions than water. The quantity $(1 - R)$ is the relative anion exclusion volume. The exclusion volume-per-unit mass of soil can also be estimated as

$$V_{ex} = \int \left(1 - \frac{c}{C_o} \right) dV \qquad (7.26)$$

where
V_{ex} is the exclusion volume (L^3 M^{-1})
c is the local concentration of the anion (M L^{-3})
C_o its bulk concentration (M L^{-3})
V is the entire volume encompassing the liquid phase per unit mass of soil

Instead of using $R < 1$, anion transport may be modeled with $R = 1$, which restricts the accessible liquid volume (Krupp et al., 1972).

Anions are also adsorbed by the soil through surface complexation and adsorption onto positively charged areas of the solid matrix. If the effect of adsorption exceeds exclusion, the anion will be retarded. The retardation factor should be viewed as an effective parameter since it quantifies a variety of adsorption and exclusion processes to which the solute (anion) is subjected.

Breakthrough curves typical for the transport of an excluded anion (Cl$^-$), a nonreactive solute (tritiated water, ^{3}H$_2$O), and an adsorbed cation (Ca^{2+}) are presented in Figure 7.4. The first two tracers pertain to transport through 30 cm columns containing disturbed Glendale clay loam soil (P.J. Wierenga, personal
FIGURE 7.4 Observed and fitted ADE breakthrough curves for three tracers typifying the transport of anions (Cl$^-$), a (nearly) nonreactive solute (^{3}H$_2$O), and an adsorbing solute (Ca^{2+}).

communication; van Genuchten and Cleary, 1982), while the Ca^{2+} data are for transport through a 30 cm long column containing a Troup loam and a Savannah fine loam (Leij and Dane, 1989). Optimizing the solutions of the ADE to the three breakthrough curves yielded R values of 0.681, 1.027, and 4.120 for Cl^-, ^3H_2O, and Ca^{2+}. Hence, the Cl^- curve was strongly affected by anion exclusion, while ^3H_2O transport was subject to very minor adsorption/exchange.

7.2.3.2 Nonlinear Adsorption

In many cases, adsorption, and hence, the retardation factor, cannot be described using a simple K_d approach. For nonlinear equilibrium adsorption, R is given as

$$R(C) = 1 + \frac{\rho_b}{\theta}\frac{\partial \Gamma}{\partial C}. \tag{7.27}$$

Two common nonlinear adsorption isotherms are the Langmuir and Freundlich equations:

$$\Gamma = \frac{k_1 C}{1 + k_2 C} \quad \text{(Langmuir)}, \tag{7.28}$$

$$\Gamma = k_3 C^n \quad \text{(Freundlich)}, \tag{7.29}$$

where k_1, k_2, k_3, and n are empirical constants. Many other equations for adsorption exist, including some that account for differences between adsorption and desorption isotherms (van Genuchten and Sudicky, 1999).

The Freundlich isotherm will be used in the following to illustrate the effects of nonlinear equilibrium adsorption on solute transport. In order to keep the calculations simple, the value of k_3 in Equation 7.29 is taken to be 0.64. Three different values of the exponent n are used, viz., 0.5, 1.0, and 1.5, to demonstrate favorable, linear, and unfavorable adsorption isotherms (Figure 7.5). Calculated distributions of the solution (C) and adsorbed (S) concentrations versus soil depth (z) 8 days after application of a 4-day long solute pulse to the soil surface are shown in Figure 7.6. The same pore water velocity is used as for the example illustrated in Figure 7.4 but with a smaller dispersion coefficient of $D = 25\,cm^2\,day^{-1}$ ($\alpha_L = 1$ cm). Notice that, as in Figure 7.4, the solution concentration distribution for $n = 1$ (linear adsorption) has a nearly symmetrical shape versus depth. The other two n values yield nonsymmetric profiles.

If $n = 0.5$, a very sharp concentration front develops, while the curve near the soil surface becomes more dispersed. The sharp front can be explained by considering the retardation factor (R) for nonlinear adsorption (Equation 7.27), which for $n = 0.5$, $\rho_b = 1.25\,g\,cm^{-3}$, $\theta = 0.40$, and $k_3 = 0.64$ leads to $R = 1 + 1/C$. This shows that R increases rapidly when C decreases with the extreme $R \to \infty$, if $C = 0$. Consequently, the apparent solute velocity $v_a = v/R$ is very small at the lower liquid concentrations but increases at higher values. Of course, higher concentrations
FIGURE 7.5 Freundlich equilibrium plots for $k_3 = 0.64$ and three values of the exponent n.
FIGURE 7.6 Effect of nonlinear adsorption on (a) solution (C) and (b) adsorbed (S) concentrations in a deep homogeneous soil profile during steady-state flow. The distributions were obtained for the three isotherms shown in Figure 7.5.

cannot move faster than lower concentrations; front sharpening will lead to a steep solute front. This front never becomes a step function because the large concentration gradient across the front will create a large diffusion/dispersion flux. If $n \ll 1$, the front may be determined from the average slope of the isotherm between the initial and the maximum aqueous concentration. In this example, those concentrations are zero and approximately $1\,g\,m^{-3}$. The average slope of the isotherm is therefore exactly the same as the linear distribution coefficient ($d\Gamma/dC = 0.64$).

Substituting this value into Equation 7.27 yields $R = 3$. Hence, the apparent solute velocity (v_a) equals 25/3 or 8.33 cm day^{-1}, and the solute front after 8 days is located at a depth of about 67 cm (Figure 7.6). Transport of favorably adsorbed solutes is frequently modeled with traveling wave solutions (van der Zee, 1990; Simon et al., 1997).

A reverse scenario occurs if $n > 1$ (unfavorable exchange). Adsorption at the lower concentrations is now relatively small and, as displayed in Figure 7.6, the toe of the front moves through the profile at a velocity nearly equal to that of an inert solute. Adsorption at the higher concentrations, on the other hand, is much more extensive, resulting in a lower apparent solute velocity in the higher range of concentrations. As a result, the concentration front becomes increasingly dispersed over time. Ignoring dispersion, the velocity of the solute front ($v_a = v/R$) at any given value of C is given by

$$v_a = \frac{v}{1 + 3\sqrt{C}}, \tag{7.30}$$

while the depth of the solute front can be approximated by

$$z(C,t) = z(C,0) + v_a t, \tag{7.31}$$

where $z(C, 0)$ is the location of a solute concentration with value C at $t = 0$.

Cation exchange processes during solute transport will involve at least two species. The simplest case arises when two cations of the same valency and total concentration such as Ca^{2+} and Mg^{2+} are considered. The resulting exchange process is then approximately linear for relatively small changes in the composition of the soil solution, that is, a change in aqueous concentration will involve a commensurate change in adsorbed concentration. Exchange between Na^+ and Ca^{2+}, on the other hand, is considerably more nonlinear. Equations that quantify the exchange reaction have been proposed by Gapon, Kerr, Vanselow, Eriksson, and others. Typically, the soil solution will contain many different species, and their interactions with the solid soil phase will have to be simulated numerically.

7.2.4 Nonequilibrium Transport

Solute breakthrough curves for aggregated soils will exhibit asymmetrical distributions or nonsigmoidal concentration fronts. The difference in water flow in the inter- and intra-aggregate regions leads to nonequilibrium conditions for solute transport due to (transversal) gradients in the solute concentration between the regions. Depending upon the exact pore structure of the medium, asymmetry is sometimes enhanced by desaturation when the relative fraction of water residing in the marginally continuous immobile region increases. Physical nonequilibrium transport due to different flow regimes is often modeled by partitioning the liquid phase into two flow domains with diffusive solute transfer between them. Similarly, differences in sorption

of solutes by various domains of the solid phase may lead to chemical nonequilibrium transport. This may also be described with a two-domain model; sorption occurs instantaneous in the equilibrium domain and is a rate-limited process for the remainder of the sorption sites of the solid phase. It is not always possible to differentiate between physical and chemical nonequilibrium since many sorption sites are only accessible after diffusion through the immobile region of the liquid phase.

In the following, nonequilibrium transport will be described with a two-domain model with a separate liquid or sorbed concentration for each domain, that is, the two-region model for physical and the two-site model for chemical nonequilibrium. The equilibrium ADE (Equation 7.19) can be readily modified for this purpose. The same dimensionless mathematical formulation can be used for physical and chemical nonequilibrium models. If necessary, the ADE can be modified to incorporate additional nonequilibrium processes and continua.

7.2.4.1 Physical Nonequilibrium

Consider one-dimensional solute movement in an isotropic soil with uniform flow and transport properties during steady flow and assume that the solute is subject to linear retardation, that is, equilibrium sorption can be described with a linear exchange isotherm. The physical nonequilibrium approach is based on a partitioning of the liquid phase into a mobile or flowing region and an immobile or stagnant region. Solute movement in the mobile region occurs by both advection and dispersion, whereas solute exchange between the two regions occurs by first-order diffusion (Coats and Smith, 1964). Following van Genuchten and Wierenga (1976), the governing equations for the two region model are as follows:

$$(\theta_m + f\rho_b K_d)\frac{\partial C_m}{\partial t} = \theta_m D_m \frac{\partial^2 C_m}{\partial x^2} - \theta_m v_m \frac{\partial C_m}{\partial x} - \alpha(C_m - C_{im}), \tag{7.32}$$

$$\left[\theta_m + (1-f)\rho_b K_d\right]\frac{\partial C_{im}}{\partial t} = \alpha(C_m - C_{im}), \tag{7.33}$$

where
f represents the fraction of sorption sites in equilibrium with the fluid of the mobile region
α is first-order mass transfer coefficient (T^{-1})
subscripts m and im, respectively, refer to the mobile and immobile liquid regions (with $\theta = \theta_m + \theta_{im}$), while ρ_b and K_d are the soil bulk density and distribution coefficient for linear sorption

Transport Equation 7.32 follows directly from addition of a source/sink term (R_s) to Equation 7.19.

Anion exclusion can be viewed as a particular example of physical nonequilibrium, the exclusion volume roughly corresponds to the immobile region (Krupp et al., 1972). The physical

nonequilibrium concept may, therefore, be adapted to describe transport of excluded anions (van Genuchten, 1981) instead of using a retardation factor of less than 1.

7.2.4.2 Chemical Nonequilibrium

Sorption of solute, especially for organic chemicals, has often been described with a combined equilibrium and kinetic sorption expression so as to better simulate transport in soils with a wide variety of soil constituents (clay minerals, organic matter, and oxides). The lack of an instantaneous equilibrium for the sorption process is sometimes referred to as chemical nonequilibrium. This terminology is somewhat misleading since the rate of adsorption or exchange is usually determined mostly by physical phenomena such as diffusion through the liquid film around soil particles and inside the aggregates (Boyd et al., 1947; Sparks, 1989).

The simplest and by far most popular approach distinguishes between type 1 sites, with instantaneous adsorption, and type 2 sites, where adsorption obeys a kinetic rate law (Selim et al., 1976). In the case of first-order kinetics, the general adsorption rates can be given with a model similar to Equations 7.20 and 7.21 as

$$\frac{\partial S_1}{\partial t} = \alpha_1 \left[\Gamma_1(C) - S_1 \right], \tag{7.34}$$

$$\frac{\partial S_2}{\partial t} = \alpha_2 \left[\Gamma_2(C) - S_2 \right], \tag{7.35}$$

where

α is again a rate constant (T^{-1})

S is the actual adsorbed concentration (M M^{-1})

Γ is the final adsorbed concentration at equilibrium as prescribed by the adsorption isotherm

subscripts 1 and 2 refer to the type of adsorption site $\Gamma_1 + \Gamma_2 = \Gamma$

Because type 1 sites are always at equilibrium, $S_1 = \Gamma_1$ and Equation 7.34 can further be ignored. The transport equation becomes

$$\frac{\partial C}{\partial t} + \frac{\rho_b}{\theta}\frac{\partial \Gamma}{\partial t} + \frac{\alpha_2 \rho_b}{\theta}(\Gamma_2 - S_2) = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x}. \tag{7.36}$$

If the fraction of exchange sites that is at equilibrium (type 1) equals f and if equilibrium adsorption is governed by the same linear isotherm for both types 1 and 2 ($\Gamma_1 = \Gamma_2$) then

$$\Gamma_1 + \Gamma_2 = fK_dC + (1-f)K_dC. \tag{7.37}$$

Of course, nonlinear equilibrium isotherms may also be used in nonequilibrium transport models. The complete transport problem can now be written as

$$\left(1 + \frac{\rho_b fK_d}{\theta}\right)\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x} - \frac{\alpha\rho_b}{\theta}\left[(1-f)K_dC - S_2\right], \tag{7.38}$$

$$\frac{\partial S_2}{\partial t} = \alpha\left[(1-f)K_dC - S_2\right], \tag{7.39}$$

where the subscript for α has been dropped. This two-site chemical nonequilibrium model reduces to a one-site kinetic nonequilibrium model by setting $f = 0$. The two-site chemical nonequilibrium model was applied successfully to describe solute breakthrough curves by Selim et al. (1976), van Genuchten (1981), and Nkedi-Kizza et al. (1983), among others.

7.2.4.3 General Nonequilibrium Formulation

The two-site and the two-region nonequilibrium models can be cast in the same (dimensionless) model according to Nkedi-Kizza et al. (1984):

$$\beta R\frac{\partial C_1}{\partial T} = \frac{1}{P}\frac{\partial^2 C_1}{\partial X^2} - \frac{\partial C_1}{\partial X} + \omega(C_2 - C_1), \tag{7.40}$$

$$(1-\beta)R\frac{\partial C_2}{\partial T} = \omega(C_1 - C_2), \tag{7.41}$$

where

β is a partition coefficient

R is a retardation factor

C_1 and C_2 are dimensionless equilibrium and nonequilibrium concentrations

T is time

X is distance

P is the column Peclet number

ω is a mass transfer coefficient

subscripts 1 and 2 refer to the equilibrium and nonequilibrium phases, respectively

The common dimensionless parameters are defined using an arbitrary characteristic concentration (C_o) and length (L):

$$T = \frac{vt}{L}, \quad X = \frac{x}{L}, \quad P = \frac{vL}{D}, \quad R = 1 + \frac{\rho_b K_d}{\theta}. \tag{7.42}$$

For the physical nonequilibrium model, the remaining dimensionless parameters are

$$\beta = \frac{\theta_m + f\rho_b K_d}{\theta + \rho_b K_d}, \quad \omega = \frac{\alpha L}{\theta v}, \quad C_1 = \frac{C_m}{C_o}, \quad C_2 = \frac{C_{im}}{C_o}, \tag{7.43}$$

whereas for the chemical nonequilibrium model:

$$\beta = \frac{\theta_m + f\rho_b K_d}{\theta + \rho_b K_d}, \quad \omega = \frac{\alpha(1-\beta)RL}{v}, \quad C_1 = \frac{C}{C_o}, \quad C_2 = \frac{S_2}{(1-f)K_dC_o}. \tag{7.44}$$

In the chemical engineering literature, $\alpha L/v$ is known as the Damköhler number; it quantifies the rate of the reaction or exchange relative to advective transport.

7.3 Solutions of the Advection–Dispersion Equation

The research and management of solute behavior in soils almost invariably require that the temporal and spatial solute distribution be known. Solute distributions as a function of time and/or space can be estimated with a variety of analytical and numerical solutions of the ADE, some of which will be briefly reviewed in the following.

7.3.1 Basic Concepts

A complete mathematical formulation of the transport problem requires that the pertinent-dependent variable or concentration type is used and that the proper auxiliary conditions are specified.

7.3.1.1 Concentration Types

Concentration is conventionally defined as the amount of solute-per-unit volume of the liquid. Since microscopic concentrations are based on a relatively small scale, a concentration at a larger scale needs to be introduced to allow use of the ADE, which is based on larger macroscopic variables and parameters. For this purpose, a macroscopic resident or volume-averaged concentration (C_R) is defined as

$$C_R = \frac{1}{\Delta V} \iiint c \, dV, \tag{7.45}$$

where

c is the variable local-scale (microscopic) concentration (M L^{-3})
ΔV is some representative elementary volume (Bear and Verruijt, 1987)

A different concentration type may be encountered at soil boundaries where the concentration is implicitly determined or defined as the ratio of the solute flux (J_s) and water flux (J_w) densities,

$$C_F = \frac{J_s}{J_w}, \tag{7.46}$$

with C_F as the flux-averaged concentration. This concentration represents the mass of solute-per-unit volume of fluid passing through a soil cross section during an elementary time interval (Kreft and Zuber, 1978). For a one-dimensional solute flux consisting of an advective and a dispersive component, the flux-averaged concentration can be derived from the resident concentration according to the transformation:

$$C_F = C_R - \frac{D}{v} \frac{\partial C_R}{\partial x}. \tag{7.47}$$

Conversely, the resident concentration may also be determined from the flux-averaged concentration. For solute application to an initially solute-free medium, the transformation is (van Genuchten et al., 1984)

$$C_R(x,t) = \frac{v}{D} \exp\left(\frac{vx}{D}\right) \int_x^\infty \exp\left(-\frac{v\xi}{D}\right) C_F(\xi,t) d\xi. \tag{7.48}$$

The difference between C_R and C_F is usually small, except when the second term on the right-hand side of Equation 7.46 is relatively large. It should be noted that a distinction between flux and resident type can be made for both the application and the detection of solutes (Kreft and Zuber, 1978, 1986). Resident concentrations are used for solute detection with, for example, time domain reflectometry, and to specify most initial conditions. Flux-averaged concentrations, on the other hand, are used for effluent samples, and to specify the influent concentration in most boundary value problems. Unless stated otherwise, it is assumed that solute concentrations are of the resident type.

Averaged concentrations can also be defined in terms of the observation scale, the latter exceeding the macroscopic scale associated with using the ADE. A time-averaged concentration (C_t) is obtained by averaging over a time interval (Δt) about a discrete time (t_o) (Fischer et al., 1979):

$$C_t(x,t_o) = \frac{1}{\Delta t} \int_{t_o - \Delta t/2}^{t_o + \Delta t/2} C(x,t) dt, \tag{7.49}$$

where C is a continuous solution of the solute concentration, which can be obtained by solving the ADE. This type of concentration occurs if solute breakthrough curves are measured using, for example, fraction collectors or gamma-ray attenuation. Similarly, a one-dimensional spatial average can be defined as

$$C_x(x_o,t) = \frac{1}{\Delta x} \int_{x_o - \Delta x/2}^{x_o + \Delta x/2} C(x,t) dx. \tag{7.50}$$

This concentration may be used to describe experimental results obtained for samples with centroid (x_o) and length (Δx). This situation occurs, for example, when the measured concentration of a large core sample is to be modeled as a point value (Leij and Toride, 1995).

7.3.1.2 Boundary and Initial Conditions

Initial and boundary conditions need to be specified in order to obtain a meaningful solution of the ADE. For a finite or semi-infinite soil, the initial condition can be formulated as

$$C(x,0) = f(x) \quad x \geq 0, \tag{7.51}$$

where $f(x)$ is an arbitrary function. Initial concentrations are almost invariably of the resident type.

The selection of the most appropriate boundary conditions for a transport problem is a somewhat esoteric topic that has received considerable attention in the literature. This is partly due to a lack of detailed experimental information for evaluating and applying boundary conditions, and inherent shortcomings of the transport equation itself at boundaries. Many transport problems involve the application to the soil of a solute, whose influent concentration may be described by a function $g(t)$. The application method may be pumping, ponding, or sprinkling. Two different types of inlet conditions are used, which assume either continuity in solute concentration or solute flux density. Simultaneous use of both conditions is seldom possible. It is generally more desirable to ensure mass conservation in the whole system than a continuous concentration at the inlet. The solute fluxes at the inlet boundary are, therefore, equated to obtain the following third or flux-type inlet condition:

$$\left(vC - D\frac{\partial C}{\partial x} \right)_{x=0^+} = vg(t) \quad t \geq 0, \tag{7.52}$$

where 0^+ indicates a position just inside the soil. It is assumed that there is no dispersion outside the soil. The alternative condition requires the concentration to be continuous across the interface at all times. At smaller scales, such continuity will likely exist. However, at the scale of the ADE, it appears difficult to maintain a constant concentration at the interface, particularly during the initial stages of solute displacement for low influent fluxes and high dispersive fluxes in the soil. Mathematically, the first or concentration-type condition is expressed as

$$C(0,t) = g(t) \quad t \geq 0. \tag{7.53}$$

The outlet condition can be defined as a zero gradient at a finite or infinite distance from the inlet. The infinite outlet condition,

$$\frac{\partial C}{\partial x}(\infty,t) = 0 \quad t \geq 0, \tag{7.54}$$

is more convenient for mathematical solutions than the finite condition,

$$\frac{\partial C}{\partial x}(L^-,t) = 0 \quad t \geq 0. \tag{7.55}$$

The use of Equation 7.54 implies that there is a semi-infinite fictitious soil layer beyond $x = L$, with identical properties as the actual soil. Such a layer does not affect the movement of the solute in the actual soil upstream of the exit boundary. Since the transport at the outlet cannot be precisely described, the intuitive contradiction of an infinite mathematical condition to describe a finite physical system is often more acceptable than using Equation 7.55, which precludes dispersion inside the soil near the outlet.

The formulation of the boundary and inlet conditions should account for the injection and detection modes in order to arrive at a mathematically consistent formulation of the problem with the same concentration type as independent variable (Parker and van Genuchten, 1984; Leij and Toride, 1995). Normally, observed or predicted resident (volume-averaged) concentrations require the use of a third-type inlet condition (also in terms of the resident concentration) whereas a first-type inlet condition is used in conjunction with flux-type concentrations.

7.3.2 Analytical Solutions

Analytical solutions can formally be obtained only for linear transport problems. It would appear that analytical solutions are not very useful for transport in field soils where there is (1) spatial and temporal variability of flow and transport parameters, (2) transient flow, especially for unsaturated soils, and (3) nonuniformity in the boundary and initial conditions. However, analytical solutions can still be quite valuable. A nonlinear transport problem may be linearized through a suitable transformation to obtain a problem for which an analytical solution is available. Also, analytical solutions provide quick estimates of solute behavior over large temporal and spatial scales while they may offer insight into the underlying transport processes. Moreover, there is usually a lack of input parameters for field problems, which diminishes the advantage of numerical over analytical model results. Analytical solutions are also routinely used to evaluate the performance of numerical schemes. Finally, the mathematical and physical conditions tend to be well defined for laboratory settings and an analytical solution can often be used, especially to estimate transport parameters by fitting analytical solutions to experimental data (Parker and van Genuchten, 1984; van Genuchten and Parker, 1987).

7.3.2.1 Variable Transformation

One straightforward way to obtain an analytical solution is to transform the ADE to an equation for which a solution already exists. As an example, consider transport in an infinite system given by

$$R\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x}, \tag{7.56}$$

$$C(x,0) = \begin{cases} C_o & x < 0 \\ 0 & x > 0 \end{cases}. \tag{7.57}$$

The new coordinates

$$\xi = x - vt, \tag{7.58a}$$

$$\tau = t, \tag{7.58b}$$

transform the ADE into a heat or solute diffusion problem given by

$$R \frac{\partial C}{\partial \tau} = D \frac{\partial^2 C}{\partial \xi^2}, \qquad (7.59)$$

$$C(\xi, 0) = \begin{cases} C_o & \xi < 0 \\ 0 & \xi < 0 \end{cases}. \qquad (7.60)$$

The solution for this and many other cases can be readily found in the literature on diffusion problems (Carslaw and Jaeger, 1959; Crank, 1975):

$$C(x, t) = \frac{C_o}{2} \text{erfc}\left(\frac{Rx - vt}{\sqrt{4DRt}} \right). \qquad (7.61)$$

Warrick (2003) reviews the use of a transformation similar to Equation 7.58a for solute transport in a three-dimensional porous medium of infinite extent. Other transformations to the diffusion problem have been employed as well (Brenner, 1962; Selim and Mansell, 1976; Zwillinger, 1989). Transformation of time to a time-integrated flow variable sometimes also allows one to derive an analytical solution of the nonlinear ADE for transient flow (Wierenga, 1977; Parker and van Genuchten, 1984; Huang and van Genuchten, 1995).

7.3.2.2 Laplace Transformation

The ADE is commonly solved directly with the method of Laplace transforms. The solution procedure will be illustrated here for an initially solute-free semi-infinite soil with a constant solute flux (vC_o) or concentration (C_o) at the inlet boundary. The mathematical problem consists of solving the ADE given by Equation 7.56 subject to

$$C - \delta \frac{D}{v} \frac{\partial C}{\partial x} = vC_o \quad \delta = \begin{cases} 0 & \text{first type} \\ 1 & \text{third type} \end{cases}, \qquad (7.62)$$

$$\frac{\partial C}{\partial x}(\infty, t) = 0, \qquad (7.63)$$

with δ as a coefficient depending on the type of inlet condition. The Laplace transform of the solute concentration with respect to time is defined as (Spiegel, 1965)

$$\overline{C}(x, s) = \mathcal{L}\left[C(x, t) \right] = \int_0^\infty C(x, t) \exp(-st) dt, \qquad (7.64)$$

where s is the (complex) transformation variable (T^{-1}). This transformation changes the transport equation from a partial to an ordinary differential equation:

$$\frac{d^2 \overline{C}}{dx^2} - \frac{v}{D} \frac{d\overline{C}}{dx} - \frac{sR}{D} \overline{C} = 0, \qquad (7.65)$$

subject to

$$\overline{C} - \delta \frac{D}{v} \frac{d\overline{C}}{dx} = \frac{C_o}{s}, \qquad (7.66)$$

$$\frac{d\overline{C}}{dx}(\infty, s) = 0, \qquad (7.67)$$

where the bar denotes a transformed variable. The following solution for the concentration in the Laplace domain is obtained with the help of the inlet condition:

$$\overline{C}(x, s) = \frac{v}{v - \delta \lambda^- D} \frac{C_o}{s} \exp(\lambda^- s), \quad \lambda^- = \frac{v}{2D} - \left[\left(\frac{v}{2D} \right)^2 + \frac{sR}{D} \right]^{1/2}. \qquad (7.68)$$

Inversion of this solution may be done with a table of Laplace transforms, by applying the inversion theorem or by using a numerical inversion program. The solution in the Laplace domain is also convenient to obtain transformations between resident and flux-averaged concentrations such as given by Equation 7.48. Finally, it should be noted that the solution for a finite outlet condition is also possible with the Laplace transform, although a bit more cumbersome (Brenner, 1962; Leij and van Genuchten, 1995).

7.3.2.3 Equilibrium Transport

van Genuchten and Alves (1982) provided a compendium of available analytical one-dimensional solutions for a variety of mathematical conditions and physical processes. Four common analytical solutions for a zero initial condition involving a first- or third-type inlet condition and an infinite or finite outlet condition are listed in Table 7.1. The solutions may be expressed in terms of the dimensionless variables P, T, and X (Equation 7.42). Typically, L is equal to the position of the outlet (the column length) for a finite system, whereas for a semi-infinite soil system an arbitrary length may be used.

Figure 7.7 contains solute profiles $C/C_o(X)$ according to the solutions listed in Table 7.1 using $R = 1$, $P = 5$ or 20, and $T = 0.25$ or 1. Curves are for a first- (A1) or a third-type (A2) inlet condition assuming an infinite outlet condition, or a first- (A3) or third-type (A4) inlet condition in case of finite outlet condition. The predicted profile for a first-type condition (A1, A3) for the lower Peclet number ($P = 5$) lies considerably above the line predicted for a third-type condition (A2, A4). The effect of the outlet condition is initially minor, but when the solute front reaches the outlet (L), a clear difference between a finite and an infinite outlet condition can be observed for both a first- (A1, A3) and a third-type (A2, A4) inlet condition. The simpler solution for a semi-infinite system can, in many cases, be used to approximate the solution for a finite condition; van Genuchten and Alves (1982) formulated the empirical restriction $X < 0.9 - 8/P$ on the position

TABLE 7.1 Analytical Solutions of the ADE for Different Boundary Conditions

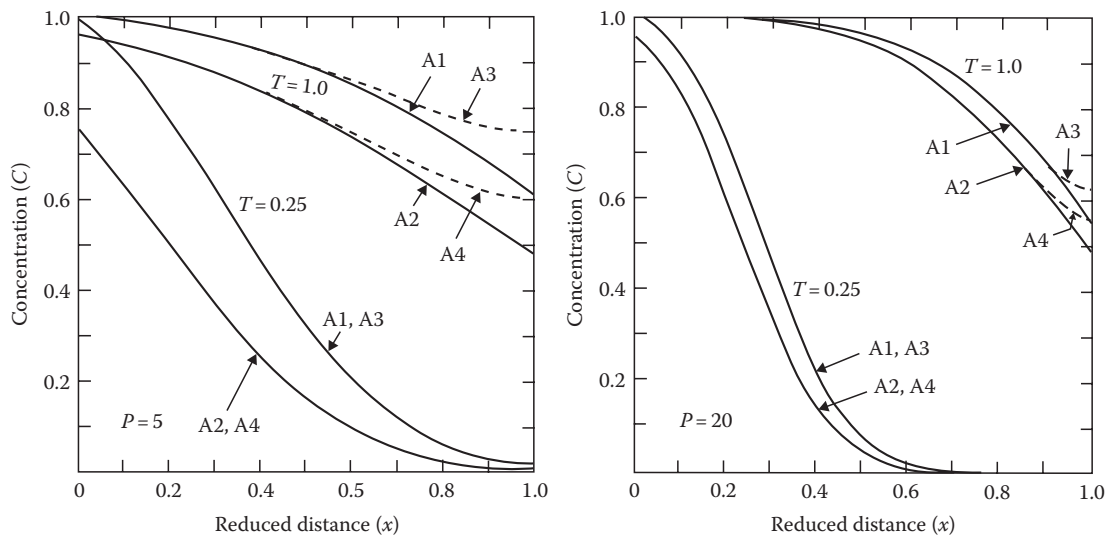
Case	Inlet Condition	Outlet Condition	Analytical Solution $C(x,t)/C_o$
A1	$C(0,t) = C_o$	$\dfrac{\partial C}{\partial x}(\infty, t) = 0$	$\dfrac{1}{2}\,\mathrm{erfc}\!\left(\dfrac{Rx - vt}{\sqrt{4DRt}}\right) + \dfrac{1}{2}\exp\!\left(\dfrac{vx}{D}\right)\mathrm{erfc}\!\left(\dfrac{Rx + vt}{\sqrt{4DRt}}\right)$
A2	$\left(vC - D\dfrac{\partial C}{\partial x}\right)_{x=0^+} = vC_o$	$\dfrac{\partial C}{\partial x}(\infty, t) = 0$	$\dfrac{1}{2}\,\mathrm{erfc}\!\left(\dfrac{Rx - vt}{\sqrt{4DRt}}\right) + \sqrt{\dfrac{v^2 t}{\pi DR}}\exp\!\left(-\dfrac{(Rx - vt)^2}{4DRt}\right) - \dfrac{1}{2}\left(1 + \dfrac{vx}{D} + \dfrac{v^2 t}{DR}\right)\exp\!\left(\dfrac{vx}{D}\right)\mathrm{erfc}\!\left(\dfrac{Rx + vt}{\sqrt{4DRt}}\right)$
A3	$C(0,t) = C_o$	$\dfrac{\partial C}{\partial x}(L, t) = 0$	$1 - \displaystyle\sum_{n=1}^{\infty} \dfrac{2\beta_n \sin\!\left(\dfrac{\beta_n x}{L}\right)\exp\!\left(\dfrac{vx}{D} - \dfrac{v^2 t}{4DR} - \dfrac{\beta_n^2 Dt}{RL^2}\right)}{\beta_n^2 + \left(\dfrac{vL}{DR}\right)^2 + \dfrac{vL}{2D}} \qquad \beta_n \cot(\beta_n) + \dfrac{vL}{2D} = 0$
A4	$\left(vC - D\dfrac{\partial C}{\partial x}\right)_{x=0^+} = vC_o$	$\dfrac{\partial C}{\partial x}(L, t) = 0$	$1 - \displaystyle\sum_{n=1}^{\infty} \dfrac{\dfrac{2vL}{D}\beta_n\left[\beta_n \cos\!\left(\dfrac{\beta_n x}{L}\right) + \dfrac{vL}{2D}\sin\!\left(\dfrac{\beta_n x}{L}\right)\right]\exp\!\left(\dfrac{vx}{D} - \dfrac{v^2 t}{4DR} - \dfrac{\beta_n^2 Dt}{RL^2}\right)}{\left[\beta_n^2 + \left(\dfrac{vL}{DR}\right)^2 + \dfrac{vL}{2D}\right]\left[\beta_n^2 + \left(\dfrac{vL}{2D}\right)^2\right]} \qquad \beta_n \cot(\beta_n) - \dfrac{\beta_n^2 D}{vL} + \dfrac{vL}{2D} = 0$


FIGURE 7.7 Plot of the concentration (C/C_o) as a function of distance (X) calculated for four different combinations of boundary conditions according to the solutions in Table 7.1 at two different times for a Peclet number of 5 and 20. (After van Genuchten, M.Th., and W.J. Alves. 1982. Analytical solutions of the one-dimensional convective–dispersive solute transport equation. USDA Tech. Bull. 1661. USDA, Washington, DC, 1982.)

for which such an approximation is reasonable. For smaller times when the solute has not reached the outlet, the finite and infinite outlet conditions obviously lead to a similar solution.

For a third-type inlet condition, the concentration at $X = 0$ just inside the soil is not equal to the influent concentration, even at time $T = 1$. Although the jump in concentration is physically odd, mass conservation is ensured. For the higher Peclet number $(P = 20)$, deviations between a first- and a third-type inlet condition are considerably reduced.

Large differences in the predicted concentration may occur if the solute front approaches the outlet at $X = 1$ or $x = L$. Calculated concentrations according to solutions A1, A2, A3, and A4 versus the Peclet number at the outlet for $T = 1$ are illustrated in Figure 7.8.

The greatest difference occurs for small Peclet numbers, namely, when hydrodynamic dispersion is relatively important. The nature of hydrodynamic dispersion suggests that C/C_o should be approximately 0.5 for $X = T = R = 1$, the average of the zero initial concentration and the influent concentration (C_o). Because of the effect of the boundary conditions, this only happens when the Peclet number exceeds 10 or more, depending on the type of solution. For the first-type inlet condition (A1, A3), C/C_o exceeds 0.5 at low Peclet numbers since a considerable amount of solute is forced to diffuse into the column to establish a constant inlet concentration.

Finally, for displacement experiments involving finite columns, it may be of interest to quantify the amount of solute
FIGURE 7.8 Solute concentration predicted with solutions A1, A2, A3, and A4 as a function of the Peclet number at $T = 1$ and $X = 1$. (After van Genuchten, M.Th., and W.J. Alves. 1982. Analytical solutions of the one-dimensional convective–dispersive solute transport equation. USDA Tech. Bull. 1661. USDA, Washington, DC, 1982.)

that can be stored in the liquid and sorbed phases of the soil (Equation 7.24). When, beginning at $t = 0$, a solution with concentration (C_o) is applied to a soil column, holdup can be defined as (Nauman and Buffham, 1983)

$$H = \frac{v}{L} \int_0^\infty \left[1 - \frac{C(L,t)}{C_o} \right] dt. \qquad (7.69)$$

The holdup is determined by the area above the breakthrough curves, that is, by integrating the "complementary" solute concentration versus dimensionless time. van Genuchten and Parker (1984) showed that $H = R$ for solutions A1 and A4, $H = R[1 + (1/P)]$ for solution A2, and $H = R\{1 - (1/P) [1 - \exp(-P)]\}$ for solution A3. In case of anion exclusion, the relative exclusion volume equals $1 - R$ and the column holdup will be less than 1.

7.3.2.4 Nonequilibrium Transport

Analytical solutions for two-domain nonequilibrium transport have been presented by, among others, Lindstrom and Narasimhan (1973), Lindstrom and Stone (1974), Lassey (1988), and Toride et al. (1993). The boundary value problem involving solute application with a constant concentration may be specified by Equations 7.40 and 7.41 subject to the following conditions:

$$C_1(X,0) = C_2(X,0) = 0, \qquad (7.70)$$

$$\left(C_1 - \frac{1}{P} \frac{\partial C_1}{\partial X} \right)_{X=0^+} = 1, \qquad (7.71)$$

$$\frac{\partial C_1}{\partial X}(\infty, T) = 0. \qquad (7.72)$$

Solutions for the equilibrium and nonequilibrium concentrations are

$$C_1 = \int_0^T J(a,b)G(X,\tau)d\tau, \qquad (7.73)$$

$$C_2 = \int_0^T \left[1 - J(b,a) \right] G(X,\tau)d\tau, \qquad (7.74)$$

where the auxiliary (equilibrium) function $G(X, \tau)$ for resident concentrations is defined as

$$G(X,\tau) = \sqrt{\frac{P}{\pi\beta R\tau}} \exp\left(-\frac{(\beta RX - \tau)^2}{4\beta R\tau/P} \right) - \frac{P}{2\beta R} \text{erfc}\left(-\frac{\beta RX + \tau}{\sqrt{4\beta R\tau/P}} \right), \qquad (7.75)$$

and for flux-averaged concentrations by

$$G(X,\tau) = \sqrt{\frac{\beta RPX^2}{4\pi\tau^3}} \exp\left(-\frac{(\beta RX - \tau)^2}{4\beta R\tau/P} \right). \qquad (7.76)$$

Furthermore, J denotes Goldstein's J function (Goldstein, 1953), which is given by

$$J(a,b) = 1 - \exp(-b) \int_0^a \exp(-x)I_0(2\sqrt{ab})d\xi, \qquad (7.77)$$

with I_0 as the zero-order modified Bessel function. The variables a and b are given by

$$a = \frac{\omega\tau}{\beta R}, \qquad (7.78a)$$

$$b = \frac{\omega(T - \tau)}{(1 - \beta)R}. \qquad (7.78b)$$

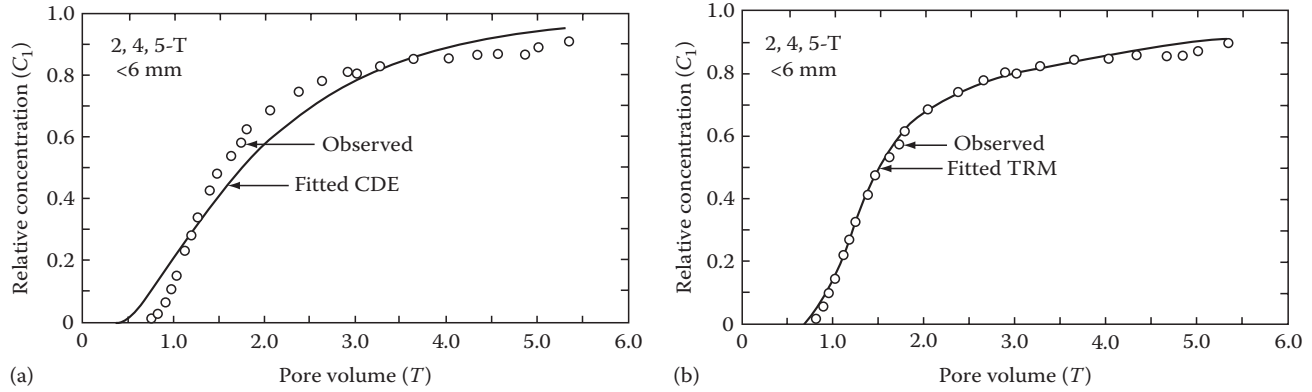
The above solution for a flux-averaged concentration was used to describe breakthrough data for the pesticide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) as observed from a 30 cm long column containing a Glendale clay loam with soil aggregates with a diameter of up to 6 mm (van Genuchten and Parker, 1987). The two-region model (TRM) three adjustable parameters (P, R, ω) provided an excellent description of the data (Figure 7.9b). The retardation factor (R) was estimated independently, using


FIGURE 7.9 Observed and fitted effluent curves for 2,4,5-T movement through Glendale clay loam. The fitted curves were based on (a) the equilibrium ADE or CDE and (b) the nonequilibrium ADE or TRM.

the distribution coefficient obtained from batch experiments, according to Equation 7.23. Using the ADE fit with P (Figure 7.9a), or P and R (not shown), as adjustable parameters resulted in a poor description of the data.

As pointed out by van Genuchten and Dalton (1986), the main disadvantage of the first-order physical nonequilibrium approach is the obscure dependency of the transfer coefficient (α or ω) on the actual diffusion process in the aggregate, particularly the value for the diffusion coefficient and the aggregate geometry. The diffusion process may be modeled for well-defined structured or aggregated porous media to allow a better description of the concentration distribution inside the aggregate. Analytical solutions are available for several aggregate geometries. The simplified immobile concentration, which is used in the general nonequilibrium formulation, can always be obtained by averaging the more detailed solution over the aggregate volume.

7.3.2.5 Time Moments

Moments are frequently used to characterize statistical distributions such as those of solute particles (concentrations) versus time or position. Analytical expressions for lower order moments are sometimes derived for deterministic transport models, especially when a direct analytical solution may be difficult to obtain. Moment analysis is more widely employed in stochastic than deterministic transport models since the uncertainty in both model parameters and predicted results is most conveniently quantified with moments. Only time moments will be considered here.

The pth (time) moment of the breakthrough curve, as obtained, say, from effluent samples collected from a soil column (with length $x = L$) to which a solute pulse is applied during steady water flow, is defined as

$$m_p(L) = \int_0^\infty t^p C(L,t)dt \quad (p = 0,1,2,\ldots). \tag{7.79}$$

The zero moment is proportional to the total solute mass, the first moment quantifies the mean displacement, the second moment is indicative of the variance (dispersion), whereas the

third moment quantifies the asymmetry or skewness of the breakthrough curve. Normalized moments (μ_p) are obtained as follows:

$$\mu_p = \frac{m_p}{m_0}. \tag{7.80}$$

The mean breakthrough time is given by μ_1. Central moments are defined with respect to this mean according to

$$\mu'_p(L) = \frac{1}{m_0}\int_0^\infty (t - \mu_1)^p C(L,t)dt. \tag{7.81}$$

The variance of a breakthrough curve, which can be used to assess solute dispersion, is given by the second central moment μ'_2. The degree of asymmetry of the breakthrough curve is indicated by its skewness $\mu'_3/(\mu'_2)^{3/2}$.

The previous definitions are employed to obtain numerical values for moments from experimental results. Substitution of an analytical solution for the solute concentration into the definitions allows the derivation of algebraic expressions for time moments. Values for transport parameters can be obtained by equating numerical and algebraic moments (Jacobsen et al., 1992; Leij and Dane, 1992). This procedure is not reliable if experimental moments of higher order ($p > 2$) are needed since even small deviations, at larger times, between experimental and modeled concentrations will greatly bias such moments.

Algebraic moments are normally obtained using the solution for the concentration in the Laplace domain. The following equality can be established from properties of the Laplace transform (cf. Aris, 1958; van der Laan, 1958):

$$m_p(x) = (-1)^p \lim_{s \to 0} \frac{d^p \overline{C}(x,s)}{ds^p}, \tag{7.82}$$

where, as before,
$\overline{C}(x, s)$ is the concentration in the Laplace domain
s is the (complex) transformation variable

Expressions for moments can hence be obtained by differentiating the solution in the Laplace domain and evaluating the result for $s = 0$. This task is conveniently handled by mathematical software.

Time moments will now be considered for three different transport problems. First, the mathematical problem for physical nonequilibrium transport can be written as

$$\theta_m R \frac{\partial C_m}{\partial t} + \theta_{im} R \frac{\partial C_{im}}{\partial t} = \theta_m D_m \frac{\partial^2 C_m}{\partial x^2} - \theta v \frac{\partial C_m}{\partial x}, \quad (7.83)$$

$$\theta_{im} R \frac{\partial C_{im}}{\partial t} = \alpha(C_m - C_{im}). \quad (7.84)$$

The conditions for instantaneous solute application to a soil are

$$C(x,0) = 0 \quad 0 \le x < \infty, \quad (7.85)$$

$$C(0,t) = \frac{m_0}{v}\delta(t), \quad (7.86)$$

$$\frac{\partial C}{\partial X}(\infty, t) = 0, \quad (7.87)$$

where

m_0 is the solute mass that is applied per unit area of soil solution at $t = 0$

$\delta(t)$ is the Dirac delta function (T^{-1})

The first-type inlet condition is used to describe flux-averaged concentrations such as effluent samples from column displacement experiments. Second, the equilibrium problem is defined by the same set of equations by setting $\theta_m = \theta$, $\theta_{im} = 0$, and $\alpha \to 0$. Third, the chemical nonequilibrium transport equations are as follows:

$$\frac{\partial C}{\partial t} + \frac{\rho_b}{\theta}\frac{\partial S}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x}, \quad (7.88)$$

$$\frac{\partial S}{\partial t} = \alpha(K_d C - S). \quad (7.89)$$

These equations are also subject to boundary and initial conditions in Equations 7.85 through 7.87.

Formulas for the mean breakthrough time (μ_1) and the variance (μ_2) of the breakthrough curve predicted for these three models are presented in Table 7.2 for a first-type inlet condition, which should be employed if effluent samples are analyzed (i.e., flux-averaged concentrations). The expressions suggest that nonequilibrium conditions do not affect the mean travel time but they do increase solute spreading. Since only the solution in the Laplace domain is needed, moment analysis is particularly useful for more complex transport problems to study the general behavior of the breakthrough curve.

TABLE 7.2 Mean Breakthrough Time (μ_1) and Variance (μ_2') for the Equilibrium and Nonequilibrium Solution of the ADE at a Distance x from the Inlet as a Result of a Dirac Delta Input Described with a First-Type Inlet Condition

ADE Model	Mean Breakthrough Time, μ_1	Variance, μ_2'
Equilibrium	$\dfrac{Rx}{v}$	$\dfrac{2DR^2 x}{v^3}$
Nonequilibrium		
Two-region	$\dfrac{Rx}{v}$	$\dfrac{2\theta_m D_m R^2 x}{\theta v^3} + \dfrac{2\theta(1-\beta)^2 R^2 x}{\alpha v}$
Two-site	$\dfrac{Rx}{v}$	$\dfrac{2DR^2 x}{v^3} + \dfrac{2(1-\beta)Rx}{\alpha v}$

7.3.3 Numerical Solutions

The solution of many practical transport problems requires the use of numerical methods because of changes in water saturation (as the result of irrigation, evaporation, and drainage), spatial and temporal variability of soil properties, or complicated boundary and initial conditions. Numerical methods are based on a discretization of the spatial and temporal solution domain and subsequent calculation of the concentration at discrete nodes in the domain. This approach is in contrast with analytical methods, which offer a continuous description of the concentration. In some cases, a combination of analytical and numerical techniques may be employed (Sudicky, 1989; Moridis and Reddell, 1991; Li et al., 1992).

The accuracy of the numerical results depends on the input parameters, the approximation of the governing partial differential equation, the discretization, and implementation of the numerical solution in a computer code solving the simulated problem. Numerous texts exist on the numerical modeling of flow and transport in porous media (Pinder and Gray, 1977; Huyakorn and Pinder, 1983; Campbell, 1985; van der Heijde et al., 1985; Istok, 1989).

The many numerical methods for solving the ADE can be classified into three groups (Neuman, 1984): (1) Eulerian, (2) Lagrangian, and (3) mixed Lagrangian–Eulerian. In the Eulerian approach, the transport equation is discretized by the method of finite differences or finite elements using a fixed mesh. For the Lagrangian approach, the mesh deforms along with the flow while it is stable in a moving coordinate system. A two-step procedure is followed for a mixed approach. First, advective transport is solved using a Lagrangian approach and concentrations are obtained from particle trajectories. Subsequently, all other processes including sinks and sources are modeled with an Eulerian approach using finite elements, finite differences, etc.

The method of finite differences (Bresler and Hanks, 1969; Bresler, 1973) and the Galerkin method of finite elements (Gray and Pinder, 1976; van Genuchten, 1978) belong to the first group as do the previously mentioned combination of analytical and numerical techniques. The finite difference and finite element

methods were the first numerical methods used for solute transport problems and, in spite of their problems discussed below, are still the most often utilized methods. Numerical experiments have shown that both methods give very good results if significant dispersion exists as quantified with the Peclet number. If advection is dominant, however, numerical oscillations may occur for both methods and small spatial increments should be used. It may not always be possible to decrease the spatial step size due to the associated increase in computations, and a variety of approaches have been developed to overcome the oscillations (Chaudhari, 1971; van Genuchten and Gray, 1978; Donea, 1991).

Lagrangian solution methods will result in very few numerical oscillations (Varoglu and Finn, 1982). However, Lagrangian methods, which are based on the method of characteristics, suffer from inherent diffusion and do not conserve mass. They are difficult to implement for 2D and three-dimensional problems. Instabilities resulting from inadequate spatial discretization may occur during longer simulations due to deformation of the stream function, especially if the solute is subject to sorption, precipitation, and other reactions.

The mixed approach has been applied by several authors (Konikov and Bredehoeft, 1978; Yeh, 1990). In view of the different behaviors of the diffusive (parabolic) and advective (hyperbolic) terms of the ADE, the problem is decomposed into an advection and a diffusion problem. Advective transport is solved with the Lagrangian approach while all other terms are solved with the Eulerian approach. The trajectories of flowing particles are obtained using continuous forward particle tracking (to follow a set of particles as they move through the flow domain), single-step reverse particle tracking (the initial position of particles arriving at nodal points was calculated for each time step), and a combination of both approaches. Ahlstrom et al. (1977), among others, used the random walk model to describe the movement of individual solute particles by viewing the travel distance for a particular time step as the sum of a deterministic and a stochastic velocity component.

In the following, only a brief introduction to the finite difference and finite element methods to solve transport problems is provided. Both methods encompass a wide variety of more specific numerical approaches. As a rule of thumb, the finite difference method is attractive because of its simplicity and the availability, at least early on, of handbooks and computer programs simulating flow and transport in porous media. On the other hand, the finite element method has proven to be more suitable for problems involving irregular geometries of the flow and transport problem, such as situations involving flow to drainage pipes and along sloping soil surfaces.

7.3.3.1 Finite Difference Methods

For one-dimensional transient solute transport, the dependent variable can be discretized according to

$$C(x,t) = C(i\Delta x, j\Delta t) = C_{ij} \quad (i = 0,1,2,\ldots,n; \; j = 0,1,2,\ldots,m). \quad (7.90)$$

Consider the simulation of the one-dimensional ADE for steady flow of a conservative tracer as given by Equation 7.56 with $R = 1$. Temporal and spatial derivatives are approximated with Taylor series expansions. Assume that the concentrations are known at the current time ($t = j\Delta t$) and that the objective is to calculate the concentration distribution $\{C[i\Delta x, (j + 1)t]\}$ at the next time. A forward-in-time finite difference scheme where the unknown concentration is given explicitly in terms of known concentrations is written as

$$\frac{C_{i,j+1} - C_{i,j}}{\Delta t} \approx D \frac{C_{i+1,j} - 2C_{i,j} + C_{i-1,j}}{(\Delta x)^2} - v \frac{C_{i+1,j} - C_{i-1,j}}{2(\Delta x)}. \quad (7.91)$$

On the other hand, a backward-in-time or implicit scheme is given by

$$\frac{C_{i,j+1} - C_{i,j}}{\Delta t} \approx D \frac{C_{i+1,j+1} - 2C_{i,j+1} + C_{i-1,j+1}}{(\Delta x)^2} - v \frac{C_{i+1,j+1} - C_{i-1,j+1}}{2(\Delta x)},$$

$$(7.92)$$

which contains several concentrations at the next time level. The problem is solved implicitly after combining the difference schemes of all nodes, and subsequently using a matrix equation solver. Finally, a weighted scheme can be defined as

$$\frac{C_{i,j+1} - C_{i,j}}{\Delta t}$$

$$\approx D \frac{w(C_{i+1,j+1} - 2C_{i,j+1} + C_{i-1,j+1}) + (1-w)(C_{i+1,j} - 2C_{i,j} + C_{i-1,j})}{(\Delta x)^2}$$

$$- v \frac{w(C_{i+1,j+1} - C_{i-1,j+1}) + (1-w)(C_{i+1,j} - C_{i-1,j})}{2(\Delta x)}, \quad (7.93)$$

with w being a weighting constant between 0 and 1. The scheme is said to be fully explicit for $w = 0$ and fully implicit for $w = 1$, while a Crank–Nicolson central-in-time scheme is derived if $w = 0.5$. For transient flow, the scheme becomes more complicated; the velocity (v) and water content (θ) are usually obtained by solving the Richards equation prior to solving the transport problem.

Errors associated with the discretization and the solution procedure can be evaluated by comparison with analytical results, provided that the problem can be sufficiently idealized (linearized) to permit the use of such solutions. This is true for other numerical solutions as well. For a convergent scheme, the difference between the numerical and analytical solutions should decrease if smaller space and time steps are used in the numerical solution; the difference should become zero if $\Delta x \to 0$ and $\Delta t \to 0$, barring round off and computational errors.

An even more important question relates to the stability of the finite difference approximation, namely, the degree to which the numerical solution is affected by errors that occur during the simulation. Such errors can usually not be eliminated completely; they depend on the implemented discretization,

the values of the input parameters, and the type of numerical scheme used for approximation of the governing transport equation. Errors are damped during the course of a simulation when a stable scheme is used, while unstable schemes allow such errors to grow without bounds.

Implicit systems are unconditionally stable, but their results may not be as amenable to changes in grid sizes as is the case with explicit systems. The Crank–Nicolson method offers an attractive compromise of being unconditionally stable and having a truncation error of order $O[(\Delta x)^2 + (\Delta t)^2]$. These properties imply, among other things, that a variable time step can be used independently of the spatial step to effectively balance the needs of an accurate approximation and a limited number of computations. However, oscillations near the concentration front may develop even for unconditionally stable methods due to the hyperbolic (convection) term in the solute transport equation. To avoid these oscillations, stability criteria in terms of the grid Peclet (Pe) and Courant (Cr) numbers are frequently formulated. Huyakorn and Pinder (1983) provided the following conservative guidelines for one-dimensional transport of a nonreactive solute:

$$Pe = \frac{v\Delta x}{D} < 2, \tag{7.94a}$$

$$Cr = \frac{v\Delta t}{\Delta x} < 1. \tag{7.94b}$$

For transport of a reactive solute, the retardation factor R must be included in the denominator of the Courant number.

7.3.3.2 Finite Element Methods

The application of the finite element methods for modeling solute transport in soils involves several steps, which will be briefly reviewed in a qualitative manner. The specifics of the method can be found in, among others, Huyakorn and Pinder (1983) and Istok (1989). The (spatial) solution domain should first be discretized. The finite element mesh, consisting of nodal points marking the elements, is usually tailored to the problem at hand. The selection of mesh size is a somewhat subjective process that considers the required degree of accuracy, the geometry of the problem, the ease of mesh generation, and the mathematical complexity associated with the use of a particular mesh. The shape of the finite elements is determined by the dimensionality and the geometry of the transport problem. One-dimensional elements consist of lines between nodal points along the coordinate where (one-dimensional) transport occurs. Examples of two-dimensional elements are triangles, rectangles, and parallelograms, while many different three-dimensional elements can be constructed.

A second step in implementing the finite element method is the description of the transport problem for each element. Generally, the method of weighted residuals is used to arrive at an integral formulation for the governing transport equation.

An approximate or trial solution for the concentration in each element is formulated as the weighted sum of the unknown concentration at the nodes of that element. A wide variety of so-called basis functions can be selected to assign weights to the nodes; the functions depend on the type of element being selected. The approximation for the element concentration will not be exact; substitution of the element concentration in the ADE yields an expression for this error (residual). The objective is to minimize the residual over the entire domain with some kind of weighting procedure for the elements. The method of weighted residuals forces the weighted average of the residuals at the nodes to be 0 and gives an expression for the residual of each element. After applying Green's theorem for each element, the residual can be written in matrix form.

The third step is the assembly of all element matrices into a global matrix system that contains the nodal concentrations and its temporal derivative as unknown variables.

The last step involves the solution of this global matrix equation. Since there are, in general, no obvious advantages for also using a finite element approximation for the temporal derivative, the latter is normally dealt with using the (simpler) finite difference method. The time step may be constant or variable. As noted earlier, the explicit or forward scheme ($w = 0$) is conditionally stable whereas the implicit or backward ($w = 1$) and the centered or Crank–Nicolson ($w = 0.5$) schemes are unconditionally stable. The nodal concentration can then be solved using standard numerical procedures.

7.3.3.3 Application

Numerical oscillations and dispersion are illustrated for several numerical schemes using results by Huang et al. (1997). The numerical solution of the ADE is particularly difficult for relatively sharp concentration fronts with advection-dominated transport characterized by small dispersivities (i.e., large Pe). As mentioned earlier, undesired oscillations can often be prevented with judicious space and time discretizations. A smaller grid size with $Pe < 2$ will virtually eliminate numerical oscillations. However, acceptable results may still be obtained for local Peclet numbers as high as 10 (Huyakorn and Pinder, 1983). The time step is selected based upon the Courant number.

Consider one-dimensional, steady-state flow in a soil column with $v = 4\,cm\,day^{-1}$. The column was initially free of any solute; a nonreactive solute ($C_o = 1$) was subsequently applied for 20 days. For negligible molecular diffusion and a longitudinal dispersivity ($\alpha_L = 0.02\,cm$), the grid $Pe = 100$ for a spatial increment $\Delta x = 2\,cm$. This grid Peclet number indicates that advection is the dominant mechanism for solute transport. In all calculations, the Courant number was less than 1, which is the stability condition for Eulerian methods.

The concentration predicted with four different finite element methods and with the analytical solution is shown in Figure 7.10. The first numerical method is based on the central Crank–Nicolson scheme for time with weighting constant ($w = 0.5$). Second, the analytical solution is shown as a solid line. Third, an implicit scheme ($w = 1.0$) is used. The last two numerical methods
FIGURE 7.10 Concentration profiles predicted with different numerical schemes for (a) solute infiltration ($t = 20$ days) and (b) solute leaching ($t = 30$ days).

implement upstream weighting (Huyakorn and Pinder, 1983) in the central and the implicit schemes, respectively. The results obtained with the Crank–Nicolson method have significant numerical oscillations (both overshoot and undershoot) Figure 7.10). This is not surprising given the large value for *Pe*. The oscillations are reduced by using an implicit scheme. Upstream weighting leads to very similar results for the central and implicit schemes. The oscillations are virtually eliminated but the solute profile exhibits more numerical dispersion; there is a greater discrepancy with the steep analytical profile than for the regular implicit scheme.

7.4 Stream Tube Models

Considerable errors may be made when applying deterministic methods to the field since model parameters are actually stochastic due to spatial and temporal variability, measurement errors, and different averaging scales. Usually, it is not possible or important to obtain discrete values for parameters in deterministic models of field-scale transport. Instead, transport properties and model results are described with statistical functions. Stochastic modeling is no substitute for data collection or model development but merely a method to deal with uncertainty of model parameters and complexity of flow and transport processes. The scale at which solute movement is observed or modeled is important. The averaging process associated with larger field-scale descriptions tends to filter out the variability at smaller scales.

The stochastic modeling of actual field problems is seldom possible. The stream tube model provides a possible exception (Dagan and Bresler, 1979; Amoozegar-Fard et al., 1982; Rubin and Or, 1993). The field is conceptualized as a system of parallel tubes illustrated in Figure 7.11. A process-based model is used to describe a one-dimensional, autonomous transport in each tube as a function of time and depth. Transport parameters are
FIGURE 7.11 Schematic of the stream tube model.

either deterministic or stochastic. The problem may be solved analytically at the scale of the tube and the field. The stream tube model is suitable for inverse procedures to estimate transport and statistical properties (Toride et al., 1995).

7.4.1 Model Formulation

For one-dimensional transport, the solute concentration at the outlet of a stream tube of length (L) may be written with the transfer function approach as (Jury and Roth, 1990)

$$C(L,t) = \int_0^t C(0, t - \tau) f(L, \tau) d\tau. \qquad (7.95)$$

The outlet concentration is a convolution of the input signal and the residence time distribution $f(L, \tau)$. The latter is, in effect, a probability density function (pdf) of the time a solute particle resides in the soil between $x = 0$ and L. The pdf, which has

dimension of inverse time, can be determined from experimental results or it may be a theoretical expression derived from a process-based model such as the ADE. The pdf depends mostly on the transport properties of the soil and, to a lesser extent, on the mode of solute application and detection, but not on the input and initial concentrations. For the equilibrium problem involving instantaneous solute application to a solute-free soil, the flux-averaged concentration and hence the pdf is given by

$$f(x,t) = \frac{x}{\sqrt{4\pi Dt^2}} \exp\left(-\frac{(x-vt)^2}{4Dt} \right).\qquad(7.96)$$

Note that this is a Gaussian pdf. Expressions for $f(x, t)$ derived at a particular depth can be readily used for predicting concentrations at other depths if the soil is homogeneous.

The stochastic approach is implemented by considering the (constant) column parameters as realizations of a random distribution. The (horizontal) field-averaged solute concentration is considered the ensemble average over the probability distribution. It is assumed that each random parameter obeys a distribution function that is independent of location and that the ensemble of possible concentrations may be estimated from a sufficient number of samples taken at different locations. The average concentration across the field is then identical to the ensemble average:

$$<C(x,t)> = \frac{1}{A}\iint C(x,t)dA = \lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}C_i(x,t),\qquad(7.97)$$

where

  A denotes the area of the field
  n is the number of samples
  $<\ >$ indicates an ensemble average

7.4.2 Application

Solute transport in a local-scale stream tube may be described with the one-dimensional ADE. Following Toride and Leij (1996a), the effects of heterogeneity are studied using pairs of random parameters (v and K_d). Note that the water content (θ) and bulk density (ρ_b) are the same for all stream tubes. The field-scale mean concentration (denoted by ^) is equal to the ensemble average:

$$\hat{C}(x,t) = <C(x,t)> = \iint_0^{\infty\ \infty} C(x,t;v,K_d)f(v,K_d)dv\,dK_d,\qquad(7.98)$$

where the bivariate lognormal joint probability density function $f(v, K_d)$ is given by

$$f(v,K_d) = \frac{1}{2\pi\sigma_v\sigma_{K_d}vK_d\sqrt{1-\rho_{vK_d}^2}}\exp\left(-\frac{Y_v^2 - 2\rho_{vK_d}Y_vY_{K_d} + Y_{K_d}^2}{2\left(1-\rho_{vK_d}^2\right)}\right),$$
$$(7.99)$$

with

$$\rho_{vK_d} = <Y_vY_{K_d}> = \iint_0^{\infty\ \infty} Y_vY_{K_d}f(v,K_d)dv\,dK_d,\qquad(7.100)$$

$$Y_v = \frac{\ln(v) - \mu_v}{\sigma_v},\qquad(7.101a)$$

$$Y_{K_d} = \frac{\ln(K_d) - \mu_{K_d}}{\sigma_{K_d}},\qquad(7.101b)$$

where

  μ and σ are the mean and standard deviation of the log-transformed variable, respectively

  ρ_{vK_d} is the correlation coefficient between Y_v and Y_{K_d} (K_d tends to increase with v for positive ρ_{vK_d} and to decrease with v for negative correlation)

Ensemble averages of v and K_d are given by (Aitcheson and Brown, 1963),

$$<v> = \exp\left(\mu_v + \frac{1}{2}\sigma_v^2\right),\qquad(7.102a)$$

$$<K_d> = \exp\left(\mu_{K_d} + \frac{1}{2}\sigma_{K_d}^2\right),\qquad(7.102b)$$

with coefficients of variation (CV):

$$CV(v) = \sqrt{\exp(\sigma_v^2) - 1},\qquad(7.103a)$$

$$CV(K_d) = \sqrt{\exp\left(\sigma_{K_d}^2\right) - 1}.\qquad(7.103b)$$

Based upon the detection mode of the local-scale concentration, three types of field-scale concentrations can be defined: (1) the ensemble average of the flux-averaged concentration ($<C_F>$); (2) the field-scale resident concentration $\hat{C}_R$, which is equal to the ensemble average of the resident concentration ($<C_R>$); and (3) the field-scale flux-averaged concentration ($\hat{C}_F$), which is defined as $<vC_F>/<v>$. The second type of concentration is obtained from averaging values of the resident concentration at a particular depth across the field. The third type is defined as the ratio of ensemble solute and water fluxes in a similar manner as for deterministic transport. It should be noted that $<vC_F>/<v> \neq <C_F>$ because v is a stochastic variable.

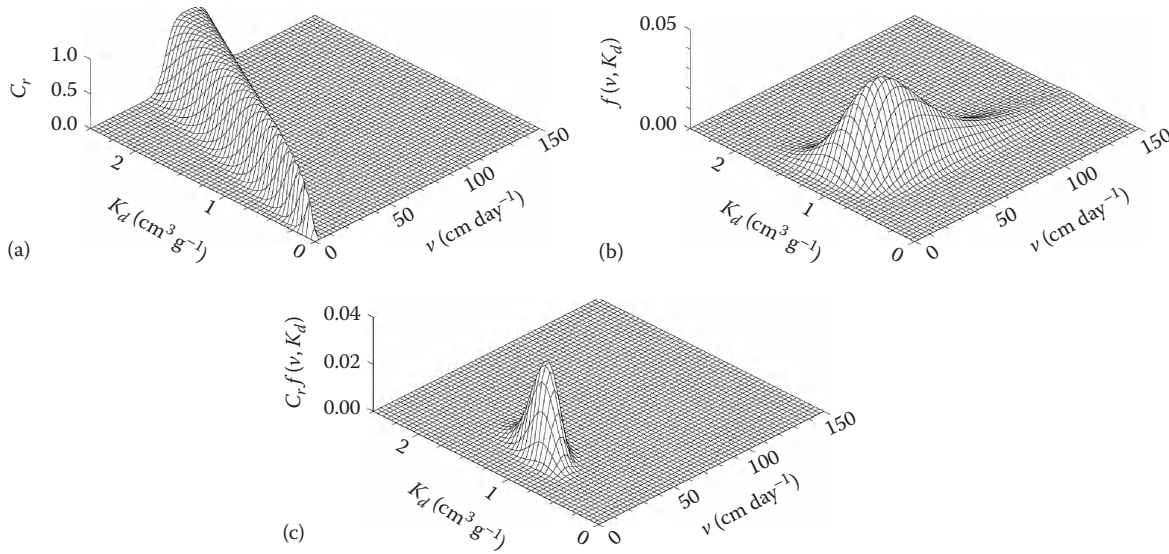
The use of the stream tube model for field-scale transport is illustrated in Figure 7.12. The local-scale concentration only depends on the particular realizations of the two stochastic parameters (v and K_d) after the independent variables (t and x) have been specified. The solution for the ADE, the resident concentration


FIGURE 7.12 Illustration of the stream tube model for field-scale transport for a two-dimensional solute application with $D = 20\,cm^2\,day^{-1}$ and $\rho_b/\theta = 4\,g\,cm^{-3}$: (a) the local-scale resident concentration as a function of v and K_d at $x = 100\,cm$ and $t = 5$ days; (b) a bivariate lognormal pdf for $\rho_{vK_d} = 0.5$, $<v> = 50\,cm\,day^{-1}$, $\sigma_v = 0.2$, $<K_d> = 1\,cm^3\,g^{-1}$, and $\sigma K_d = 0.2$; and (c) the expected concentration at $x = 100\,cm$ and $t = 5$ days.

at $x = 100\,cm$ and $t = 5$ days as a function of v and K_d is shown in Figure 7.12a and the bivariate lognormal pdf for v and K_d in Figure 7.12b; the distribution is skewed with respect to v since σ_v is fairly high; the smaller σ_{Kd} results in a more symmetric distribution for K_d. The negative ρ_{vK_d} results in an increasing v with a decreasing K_d, and vice versa. The expected concentration—again a resident or volume-average—is shown in Figure 7.12c. It is obtained by weighting the local concentration (Figure 7.12a) by multiplying it with the joint pdf (Figure 7.12b). The peak in Figure 7.12c suggests that stream tubes with approximately $v = 25\,cm\,day^{-1}$ and $K_d = 1\,cm^3\,g^{-1}$ contribute the most to solute breakthrough when $x = 100\,cm$ and $t = 5$ days. The volume of the distribution in Figure 7.12c corresponds to the ensemble average ($<C_R>$).

Variations in the local-scale concentration between stream tubes, at a particular depth and time, can be characterized by its variance. The variance across the horizontal plane is given by (Bresler and Dagan, 1981; Toride and Leij, 1996b):

$$\mathrm{Var}\left[C(x,t)\right] = \int_0^\infty \int_0^\infty \left[C(x,t) - <C(x,t)>\right]^2 f(v, K_d)\, dv\, dK_d$$

$$= <C^2(x,t)> - <C(x,t)>^2. \tag{7.104}$$

For a deterministic distribution coefficient (K_d), Equation 7.99 reduces to

$$<C(x,t)> = \int_0^\infty C(x,t;v) f(v)\, dv, \tag{7.105}$$

where the lognormal pdf for the single stochastic variable (v) is given by

$$f(v) = \frac{1}{\sqrt{2\pi}\sigma_v v} \exp\left(-\frac{\left[\ln(v) - \mu_v\right]^2}{2\sigma_v^2}\right). \tag{7.106}$$

The mean (Figure 7.13a) ($\hat{C}_R = <C_R>$) and the variance (Figure 7.13b) are shown as a function of depth for three values of σ_v at $t = 3$ days for a nonreactive solute. More solute spreading occurs in the $\hat{C}_R$ profile when σ_v increases (Figure 7.13a). The variation in the local-scale C_R also increases with σ_v, indicating a more heterogeneous solute distribution in the horizontal plane (Figure 7.13b). Because flow and transport become more heterogeneous as σ_v increases, more observations are needed to estimate $\hat{C}_R$ for $\sigma_v = 0.5$ than for $\sigma_v = 0.1$. The double peak in the variance profiles of Figure 7.13b is due to the relative minimum for this pulse application at around $x = 30\,cm$, where the highest concentration occurs.

For reactive solutes, the variability in the distribution coefficient (K_d) must also be considered. The field-scale resident concentration ($\hat{C}_R$) at $t = 5$ days is plotted versus depth in Figure 7.14 for perfect and no correlation between v and K_d. The figure shows that the negative correlation between v and K_d causes additional spreading. Such a negative correlation seems plausible since coarse-textured soils generally have a relatively high v, due to their higher hydraulic conductivity, and a small K_d, due to their lower exchange capacity. The opposite may hold for fine-textured soils. Robin et al. (1991) reported a weak negative correlation between K_d and the saturated hydraulic conductivity for a sandy aquifer.
FIGURE 7.13 The effect of variability in the pore-water velocity, v, on (a) the field-scale resident concentration profile, and (b) the distribution of the variance for $\hat{C}_R$ in the horizontal plane; for a two-dimensional application of a nonreactive solute ($R = 1$) assuming $<v> = 20\,$cm day^{-1} and $D = 20\,$cm^2 day^{-1}.
FIGURE 7.14 The field-scale resident concentration profile, $\hat{C}_R(x)$, for three different correlations between v and K_d with $<v> = 50\,$cm day^{-1}, $D = 20\,$cm^2 day^{-1}, $<K_d> = 1\,$g^{-1} cm^3, $\sigma_{Kd} = 0.2$, $<R> = 5$, and $\rho_b/\theta = 4\,$g cm^{-3}.

7.5 Nonaqueous Phase Liquids

Contamination of soil and water resources by nonaqueous phase liquids (NAPLs) has received considerable attention over the past few decades. These organic liquids have a low aqueous solubility. They are classified according to density as LNAPLs and DNAPLs, that is, lighter and denser than water. Oil and gasoline represent LNAPLs while many DNAPLs are chlorinated solvents used as cleaning (degreasing) agents or in manufacturing processes. NAPLs may be accidentally released to the soil through spillage during transport and handling operations or leakage from underground storage tanks, or they could have been disposed in the past when there was less awareness about any risks. NAPLs move downward through the vadose zone due to gravity as a separate liquid phase. A portion of the liquid will remain entrapped in the soil pores due to capillary forces forming isolated ganglia known as residual NAPL. The contaminant may partition among the solid, water, and air phases. The remaining liquid will eventually reach the water table. LNAPLs will accumulate on the water table and in the capillary fringe and, if a sufficient amount is spilled, the contaminant will spread on the water table. DNAPLs, on the other hand, will penetrate across the groundwater table and through the saturated porous medium if the spill volume is sufficient to feed the flow. Further vertical migration will be halted if the penetrating liquid encounters layers of fine-grained material such as silt or clays. In this case, the DNAPL will deflect horizontally until it reaches a more permeable vertical path or it forms a pool. Most NAPLs are slightly soluble in water and, either as entrapped in the soils or as a pool, will constitute a long-term source of groundwater pollution. The slow degradation and the extreme toxicity of many NAPLs found in groundwater make them a persistent and serious threat to human health.

Transport of NAPLs in porous media is a complex multiphase, multidimensional, and multicomponent problem (Willson et al., 2006). Further details pertaining to the multiphase transport of NAPL compounds can be found in Bear and Verruijt (1987), Miller et al. (1998), and Charbeneau (2000). Several researchers have developed mathematical models for multiphase flow and transfer between nonaqueous and aqueous phase (e.g., Kueper and Frind, 1988; Huyakorn et al., 1994; Imhoff et al., 2003; Willson et al., 2006; Fagerlund et al., 2008). Numerical models such as TOUGH2 (Pruess et al., 1999) and STOMP (White and Oostrom, 2000) are available to describe the multiphase transport of NAPLs in saturated and unsaturated media. The concern here is dissolution of static NAPL from both residual ganglia and pools and subsequent transport of the dissolved constituents in the aqueous phase by the same mechanisms of a (generic) solute that were previously reviewed.

7.5.1 Dissolution Process

Schwarzenbach et al. (1993) define dissolution as a thermodynamic process by which the molecules of an organic solute in its pure liquid phase are transferred into water. When an organic liquid is in contact with pure water, some of the organic

molecules will transfer from the organic into the water phase while some water molecules will transfer from the water into the organic phase. Upon equilibrium, the concentration of the organic molecules in the water phase equals the aqueous solubility of the compound. Partitioning of NAPL pollutants in the water phase has been described according to the local equilibrium assumption. Hence, if the organic concentration is known for one phase, it may be inferred for other phases by equilibrium partitioning relationships.

Several early laboratory experiments (van der Waarden et al., 1971; Dietz, 1978; Duffy et al., 1980) suggested the validity of the local equilibrium assumption in groundwater systems. Other studies however (Feenstra and Coburn, 1986; Sitar et al., 1987; Mercer and Cohen, 1990) note that observed concentrations can be several orders of magnitude lower than the aqueous solubility suggesting that no equilibrium conditions exist. Powers et al. (1991) found that nonequilibrium mass transfer conditions must be assumed for small contact times, large NAPL blobs, and low NAPL saturations. In terms of groundwater contamination, this implies that the duration of contamination and the volume of contaminated groundwater are much larger than that predicted by the local equilibrium assumption (Mackay et al., 1985). Powers et al. (1992) pointed out that the lower observed concentrations may be due to rate-limited mass transfer between the NAPL and the aqueous phase or to a bypassing of the water flow around the low permeability area contaminated with NAPL ganglia (Kueper and Frind, 1988). Other causes could be NAPL morphology and available surface contact area (Cho and Annable, 2005; Dobson et al., 2006; Zhao and Ioannidis, 2007), heterogeneities in the aquifer (Miller et al., 1998), or multicomponent dissolution effects (Geller and Hunt, 1993; Garg and Rixey, 1999; Brahma and Harmon, 2003). Several studies have attempted to quantify the dissolution kinetics and the NAPL–water interfacial area using photography of frozen or polymerized NAPL blobs (Powers et al., 1992; Kennedy and Lennox, 1997; Jia et al., 1999), gamma radiation (Brusseau et al., 2002), magnetic resonance (Baldwin and Gladden, 1996; Zhang et al., 2007), and x-ray microtomography (Brusseau et al., 2008).

7.5.1.1 Entrapped NAPL

In view of the inadequacy of the local equilibrium assumption, several researchers have further examined rate-limited dissolution of NAPL in saturated porous media. Most of the studies dealt with NAPL at residual saturation (Miller et al., 1990; Powers et al., 1991, 1992; Geller and Hunt, 1993; Sahloul and Chatzis, 2002). A detailed discussion of the residual NAPL dissolution mechanisms in porous media can be found in Powers et al. (1991, 1992) and in Khachikian and Harmon (2000). Dissolution from a single-component source may be described with a linear driving force model, and dissolution of an organic species from a multicomponent source will be more complicated to model. For a single component, the mass flux from the organic to the aqueous phase is proportional to the difference between the solubility of the compound and its actual aqueous concentration (Powers et al. 1992). The proportionality factor k_f is often referred to as the mass transfer coefficient, that is:

$$J = k_f(C_s - C), \qquad (7.107)$$

where
J is the mass flux [M L^{-2}T^{-1}]
C_s [M L^{-3}] is the solubility of the compound
C [M L^{-3}] is the concentration in the aqueous phase
k_f is the mass transfer coefficient [L T^{-1}]

Imhoff et al. (2003) pointed out that the mass transfer coefficient depends on the morphology of the entrapped NAPL as determined by pore structure (Powers et al., 1992) and wettability (Bradford et al., 2003), the velocity in the aqueous phase, viscosity, density (Miller et al., 1990), and NAPL saturation (Imhoff et al. 1994). The mass transfer coefficient may be predicted from regression equations, and interfacial area may be inferred or measured (Powers et al., 1991; Geller and Hunt, 1993; Bradford and Leij, 1997; Dobson et al., 2006). A lumped mass transfer rate constant equal to the product of the specific interfacial area and the mass transfer coefficient may also be used (Miller et al., 1990; Powers et al., 1992; Imhoff et al., 1994). Various correlations have been developed, which relate dimensionless groups, such as the Reynolds, Schmidt, and Peclet numbers, and residual NAPL saturation to the Sherwood number, which represents the dimensionless concentration gradient at the interface. Once the total mass transfer flux is evaluated, the term is incorporated into the classical ADE.

7.5.1.2 NAPL Pools

The description of the dissolution of NAPLs from a planar source (pools) poses special challenges. The low cross-sectional area with respect to pool volume implies slow dissolution. The merits of different conditions at the interface of pool and porous medium have been reviewed for mass transfer into pure fluids (Sherwood et al., 1975). A comparison of boundary conditions for dissolution in porous media has been lacking, in part because of a paucity of experimental data (Schwille, 1988; Voudrias and Yeh, 1994; Whelan et al., 1994; Dela Barre, 1999).

For a NAPL pool located at the water table (LNAPL) or an effectively impermeable layer (DNAPL), a concentration boundary layer develops at the organic–water interface. The thickness of the concentration boundary layer depends on the interstitial groundwater velocity, hydrodynamic dispersion, and pool size (Dela Barre, 1999). After a hydrodynamic boundary layer is established for water flow, a concentration gradient develops. In general, the NAPL–water interface and the geometry of the porous medium are difficult to determine accurately, and the dissolution process at the macroscopic scale is described via mass transfer coefficients. For flow over a NAPL pool, the local mass transfer coefficient decreases with distance from the front end of the pool and has a maximum value at the upstream edge (Chrysikopoulos and Lee, 1998). However, due to the complexity

of the subsurface environment and associated scale dependency of modeling parameters, the NAPL dissolution process is commonly described with an average mass transfer coefficient or rate constant.

Johnson and Pankow (1992) used experimental results from Schwille (1988) and the analytical solution from Hunt et al. (1988) to calculate a surface-area-averaged mass transfer rate whose value decreases as the length of the pool increases to reproduce the decreasing dissolution rate across the top of the pool. The mass transfer term was then included in the steady-state ADE, which was solved analytically for a homogeneous semi-infinite medium with a square pool of negligible thickness. Local equilibrium was assumed by selecting the aqueous solubility as boundary condition at the pool–water interface while the remaining boundary conditions away from the pool where of the Dirichlet type with fixed zero concentration.

Holman and Javandel (1996) also used the local equilibrium assumption in the transient two-dimensional ADE that describes the dissolution and transport of a mixture of slightly soluble compounds from a LNAPL pool into the groundwater. Their model describes the dissolution and transport of the contaminant as a heterogeneous reaction involving three steps: molecular diffusion of the compound inside the pool toward the LNAPL–water interface, dissolution of the compound at the interface, and transport of the dissolved compound from the interface into the aquifer.

Chrysikopoulos et al. (1994) developed a mathematical model for dissolution of a single-component rectangular DNAPL pool of negligible thickness in a two-dimensional semi-infinite homogeneous porous medium with steady-state flow, equilibrium sorption, and first-order decay. The boundary condition at the DNAPL–water interface was a second-type boundary condition. It is represented by a mass transfer relationship in which the fixed diffusive flux is related to the saturated aqueous concentration through a time-varying mass transfer coefficient. Lee and Chrysikopoulos (2002) applied the same boundary conditions to the analysis of the dissolution of a circular trichloroethylene (TCE) plume. The authors developed correlations between the time invariant overall Sherwood number and the Peclet number, which were found in good agreement with the experimental data.

Leij et al. (2000) used the ADE to model the three-dimensional equilibrium solute transport in a homogeneous porous medium generated from the dissolution of planar and parallelepipedal sources of persistent contamination. Analytical solutions were formulated based upon Green's functions for a first-, second-, and third-type boundary condition in the case of a planar source. A third-type or Cauchy-type boundary condition, which imposes a fixed total flux (diffusive and advective) at the DNAPL–water interface, more realistically predicts the concentration profiles compared with either the first-type or fixed concentration or a second-type boundary condition. Leij and van Genuchten (2000) extended Green's function method to obtain analytical solutions for nonequilibrium transport from a rectangular pool. The authors observed that the solute flux from the

pool, and therefore the concentration in the medium, depends strongly on the mass transfer coefficient.

7.5.2 Numerical Modeling

Numerical modeling of NAPL dissolution in saturated porous media has been widely investigated in the past decades. Several numerical techniques have been applied in order to enhance the performance of computer codes designed to simulate contaminant transport in the subsurface. A distinction is again made between dissolution from NAPL blobs entrapped in the pores of a saturated porous medium and from a DNAPL pool at the bottom of a saturated porous medium.

In the first case, the NAPL blobs are incorporated in the domain of interest. Therefore, the dissolution term, expressed by a first-order rate-limited relationship used by Geller and Hunt (1993) and Powers et al. (1991), among others, will be added to the ADE as a point source term. In the second case, the pool is just outside the solution domain, and NAPL dissolution is accounted for by formulating the appropriate boundary conditions.

Examples of numerical models developed to describe groundwater plumes emanating from entrapped NAPL in the subsurface can be found in Guiguer (1991) and Clement et al. (2004). Christ et al. (2009) simulated dissolution of a DNAPL (tetrachloroethylene or PCE) and mass recovery in two- and three-dimensional nonuniform permeability fields using a modified version of the popular MT3D numerical code to assess the influence of model dimensionality on the mass recovery predictions.

The numerical simulation of NAPL blobs dissolving in a saturated porous medium does not present particular difficulties when the mass transfer coefficient is considered independent of the aqueous concentration. In this case, the governing partial differential equation is linear and its solution can be achieved by using one of the numerical techniques available to solve the classical ADE. For dispersion–diffusion-dominated problems, the classical Eulerian approach either by using finite difference techniques or using Galerkin finite element methods on a fixed grid in space has performed quite satisfactorily. For advection-dominated transport problems and for pure advection problems, however, the Eulerian methods produce inaccurate solutions due to oscillation and numerical dispersion. As mentioned in Section 7.3, a way to obviate this problem is to use refined grids or higher order finite difference and finite element methods or, alternatively, to use the upstream weighted finite difference or finite element method (Settari and Aziz, 1975; Dalen, 1979). Lagrangian and mixed Lagrangian–Eulerian approaches have also been popular to solve advection-dominated transport problems (Huyakorn and Pinder, 1983). The method of characteristics and the random walk method belong to these classes of techniques. Yeh (1990) proposed an Eulerian–Lagrangian method with a zoomable hidden fine-mesh approach, which eliminates the numerical oscillations and reduces the numerical dispersion. A variety of approaches exist to combine numerical methods with analytical solutions (e.g., Hwang et al., 1985).

When the contamination in the aquifer is produced by the dissolution of NAPL pools, the process is described by the classical two or three-dimensional ADE where the presence of the pool is accounted for in the boundary conditions. This problem is also known as the patch-source problem. According to Segol (1994), the term "refers to the transport of a solute from a boundary source of finite extent into a rectangular domain subjected to a uniform, unidirectional velocity field."

The boundary conditions applied to simulate the source term are the Dirichlet or first-type boundary condition, the Neuman- or second-type boundary condition, or the Cauchy- or third-type boundary condition. Numerically, the problem of modeling solute transport with a dissolving source on the boundary is somewhat different than dissolution from a source inside the domain of integration. Segol (1994) reviewed several studies where the patch-source problem has been used to illustrate numerical techniques developed to solve the convection–dispersion equation. Daus and Frind (1985) formulated the patch-source problem using either Dirichlet or Cauchy boundary conditions. The governing equation is then solved numerically by the alternating direction Galerkin technique, which consists in splitting the governing equation into two one-dimensional ADEs coupled with cross derivatives terms. For both boundaries, the technique produces accurate results, and it is more efficient than the classical finite-element method due to the decoupling procedure. The cell analytical–numerical method was successfully applied by Elnawawy et al. (1990) to the patch-source problem with a Dirichlet boundary condition at the source. The results showed to be accurate but were obtained at the expenses of geometrical flexibility. Leismann and Frind (1989) solved the patch-source problem by applying the symmetric-matrix time integration technique. They used the Dirichlet-type boundary condition at the source. The method applied by the authors uses an integration technique for the time derivative, which produces an algebraic system of equations whose coefficient matrix is symmetric and positive definite. In this case, the resulting algebraic system can be efficiently solved. Sudicky (1989) used the patch-source problem with the source described by Dirichlet-type boundary conditions to illustrate the Laplace transform Galerkin method. In this method, the Laplace transform is first applied to the ADE to eliminate the temporal derivatives. The transformed equation is then solved for a discretized spatial domain using the standard Galerkin finite element procedure. Finally, the inversion of the transformed concentration values is obtained using Crump's method. According to the author, the method has the advantage of producing accurate and robust solutions, but it is restricted to linear mass transport in a steady flow field.

In the four studies reviewed by Segol (1994), the source term is perpendicular to the flow direction. Lee and Chrysikopoulos (1995) used a Neuman or second-type boundary condition for dissolution from a multicomponent DNAPL pool at the bottom of an aquifer with steady flow. The boundary condition corresponding to the pool location is described by a relationship in which the diffusive flux is specified using a time- and position-dependent mass transfer coefficient. The numerical scheme adopted by the authors to solve the governing equation is the classical implicit finite difference approximation, which yielded a band diagonal system of algebraic equations.

7.5.3 Remediation

Over the past decades, researchers have aimed to develop efficient techniques to remediate soil and groundwater. The simplest and commonly applied technique is known as pump-and-treat, where contaminated groundwater is extracted and treated above ground. This technique promotes a decline in contaminant concentrations over time, but it requires the treatment of large volumes of water. A combination of optimization methods and simulation models has been proposed to determine more efficient cleanup design strategies (Gorelick et al., 1993). In particular, these optimization techniques have been developed to determine the location and number of pumping wells, the optimal pumping rate (which will maximize the contaminant removal at the lowest energy cost) and treatment strategies.

Among the remediation techniques are hot-water flushing (Imhoff et al., 1995; O'Carroll and Sleep, 2007), air sparging (Adams and Reddy, 2000), cosolvent flushing (Imhoff et al., 1995), the use of surfactants (Childs et al., 2006), and in situ bioremediation (Zoller and Rubin, 2001). The effectiveness of the remediation may be substantially improved if the location and extent of the NAPL source are known.

7.5.4 Inverse Modeling to Locate Contaminant Sources

The problem of defining the location of the DNAPL pool and the release history of the contaminant (the time period and the mass at which the contaminant was released) is important to design of the most efficient cleanup strategy but also from a legal and regulatory point of view. Remediating a contaminated soil or aquifer is typically costly and cumbersome. Therefore, as Skaggs and Kabala (1994) noted, a model capable of backtracking a contaminant plume in space and time would help to individuate the responsible parties and to distribute the cleanup costs accordingly. Unfortunately, the dispersive nature of the contaminant transport problem makes it an irreversible problem. Modeling the contaminant release history by simply reversing time will result in an ill-posed problem with a nonunique or unstable solution (Skaggs and Kabala, 1994).

Another obstacle in the development of a model to identify contaminant release history is the scarcity of historical data. Due to this lack of data, reconstruction must be based on observations of the existing contaminant plume. Usually, an extensive number of observations are required in order to obtain a detailed description of the concentration profiles. Recently, several parameter identification techniques coupled with numerical models have been developed to minimize the number of locations (wells) where the NAPL concentration needs to be observed (Yeh and Sun, 1984; McCarthy and Yeh, 1990).

Several researchers have dealt in the past with the problem of contaminant source characterization (Gorelick et al., 1983; Skaggs and Kabala, 1994). Much emphasis has been given to the temporal reconstruction of the source release while the problem of locating existing DNAPL contaminant sources has been neglected, especially for those cases involving heterogeneous flow and transport fields. Hwang and Koerner (1983) explored the performance of two different approaches: nonsequential and sequential optimization. In the former the optimization process is applied to the partial differential equation describing solute transport. In the sequential optimization approach, the partial differential equation is discretized and a linear dynamic system is developed that may subsequently be optimized. Hwang et al. (1988) applied their methods to two field cases with pollution due to surface ponding of organic waste and a landfill. In both cases the estimated source location was relatively close to the actual location but the procedure was limited to two-dimensional geometries.

Gorelick et al. (1983) combined least-square regression and linear programming to obtain the least absolute error to identify the location, magnitude, and disposal period of underground pollutant point sources. The authors examined the case of steady and transient scenarios. The solution procedure was based on the response matrix approach, which assumes a linear system response. Their results showed that at steady state both the linear programming and the multiple regression formulations produced accurate results only when data were relatively noise free. In the transient case, both procedures were successful in estimating the location and magnitude of pollutant sources due to the abundance of concentration data.

Uffink (1989) and Bagtzoglou et al. (1992) applied the Random-walk method, which is based on reversing the advective part of the transport model while the dispersive part is left positive. The results provide a probability distribution of the contaminant initial position, but the approach is not able to define a contaminant release history. Simultaneous estimation of aquifer parameters and a distributed pollutant source term was attempted by Wagner (1992) by combining nonlinear maximum likelihood estimation with groundwater flow and transport models.

Sidauruk et al. (1998) presented an inverse method based on analytical solutions of contaminant transport problems to estimate mass transport parameters such as dispersion coefficients and flow velocities as well as the amount of pollutant, its initial location, and time origin. The inverse procedure is based upon the method of correlation coefficient optimization. By minimizing the correlation coefficient of the linear regression, the parameters of interest are determined by explicit formulas similar to linear regression equations. The method was applied to the two-dimensional cases of a plume generated by instantaneous and continuous point sources. As the authors pointed out, the method is restricted to simple problems involving a homogeneous porous medium, and simple geometries and flow fields.

Mahar and Datta (1997) combined optimal groundwater quality monitoring network design and point-source identification algorithms to estimate the magnitude, location, and active duration of a pollutant source using a three-step procedure.

In the first step, a nonlinear optimal source identification model with embedded flow and transport simulation constraints is employed to identify source fluxes using concentration data for arbitrary locations. The results from this preliminary step are then perturbed statistically, to account for uncertainties in measurements, and incorporated into a groundwater monitoring network design model with an integer-programming-based optimization model. The concentration data generated by the monitoring network are then fed back to the source identification model to obtain more accurate predictions.

Skaggs and Kabala (1994) applied Tikonov regularization in one-dimensional numerical experiments to recover the release history of a contaminant originated from a known site. Their method was found to be very sensitive to observation errors. In a subsequent paper, Skaggs and Kabala (1995) attempted to solve the same problem by applying the method of quasi-reversibility to the convection–dispersion equation. The method was preferable to Tikonov regularization due to its simple implementation and its capacity to include nonconstant flow and transport parameters, although it was not as accurate.

Snodgrass and Kitanidis (1997) proposed Bayesian analysis and a geostatistical approach to the problem. Their method provides a measure of the error associated with the best estimate of the release history and helps to identify sources of uncertainties. One limitation is that the location of the contaminant source has to be known a priori. The same assumption was made by Kondisetty et al. (1996) in an inverse optimization approach to analytically track instantaneous point-source releases in the saturated zone. The inverse approach, based on the minimization of the error in the difference between calculated data and observations, was coupled with a two-dimensional transport model using the method of characteristics.

An attempt to extend the release history problem to three-dimensional domains and spatially distributed sources was presented by Woodbury et al. (1998). The authors applied the minimum entropy method to recover the source-release history of a three-dimensional plume generated by a rectangular first-type patch source. Their work is carried out in an analytical framework, and it is limited to steady flow in a uniform porous medium. Liu and Ball (1999) applied inverse modeling to estimate the contaminant plume history from observed concentrations at a field site that was being remediated. The authors estimated the contaminant boundary concentration by assuming a simple mass-conserving two-layer diffusion model. They used least-square minimization where the objective function was regularized by adding a term to smooth the boundary concentration.

Sciortino et al. (2000) developed an inverse model procedure to determine the size and the location of a single-component DNAPL pool in a saturated homogeneous porous medium for steady flow. The inverse problem was solved using least-squares minimization with a search procedure based on the Levenberg–Marquardt method. A three-dimensional analytical model was used to describe the transport of solute from a dissolving DNAPL pool. The algorithm was tested to predict the location and size of a DNAPL pool placed in a controlled three-dimensional

bench-scale experiment. The Levenberg–Marquardt algorithm was used to minimize (1) ordinary residuals, (2) residuals with weights equal to the square of the inverse of the observations, and (3) residuals with weights obtained by adding a constant term to the observed concentrations. The results were found to be sensitive to the location of the observation wells and to the type of residuals minimized. The inverse problem is nonunique and nonconvex even in the absence of observation errors.

Neupauer and Wilson (1999, 2001) developed a backward location and travel-time probabilistic model to characterize source of groundwater contamination and their prior location. The authors derived the governing equation of the backward probabilities using the adjoints of the ADE modified with the addition of a load term that depends on both the type of probability that it describes (location or travel time) and the type of well (pumping or monitoring) used to detect pollution. Michalak and Kitanidis (2004) proposed a geostatistical approach combined with the adjoint state method that was able to reconstruct the historical multidimensional contaminant distribution in porous media. Recently, Yeh et al. (2007) presented the SATS-GWT approach, which consists of a combination of simulated annealing (SA), tabu search (TS), and a three-dimensional groundwater flow and solute transport model (MODFLOW-GWT). Source location, release concentration, and release period of groundwater contaminants may be estimated using the proposed model. The authors applied their model to different contamination scenarios, and they claim that the approach yields accurate estimates, even in the presence of measurement errors.

Gas Transport in Soils

Dennis E. Rolston
University of California, Davis

Per Møldrup
Aalborg University

8.1 Introduction

Understanding gas transport in soils and the vadose zone is important for evaluation of soil aeration, which is the interchange of various gases between the atmosphere and the soil and the various processes that either produce or consume gases in the soil. Soil aeration is important for plant growth since O_2 is required for root respiration. The two major gases associated with aeration are oxygen (O_2) and carbon dioxide (CO_2) where O_2 moves from the atmosphere to soil and is consumed and CO_2 is produced in soil and moves from the soil to the atmosphere. Oxygen transport through the capillary fringe in regard to reaeration of groundwater is another important area of soil-gas transport. A thorough discussion of soil aeration is given in a book by Glinski and Stepniewski (1985), Scott (2000), Jury and Horton (2004), and Rolston (2005).

In solid waste landfills, methane and carbon dioxide transport through the cover soil will likely be by both diffusion and advection affected by variations in soil moisture conditions, soil type, and soil structure, while oxygen diffusion into the cover layer will be a main control of atmospheric methane oxidation and uptake. Movement of gaseous radionuclides from radioactive waste sites is important in many areas. Understanding gas transport is also important for estimating movement of volatile organic chemicals from contaminated waste sites within the vadose zone (Baehr et al., 1989). Understanding transport of radon and its

decay products in soils and into buildings (Nazaroff, 1992) is important for evaluating the possible adverse health effects of radon gas. In a longer-term perspective, design of optimal plant growth media for use on earth or in space requires detailed knowledge of the gas diffusivity behavior in aggregated porous media including soils at both normal gravity and microgravity (Jones et al., 2003).

Gas transport in soils occurs due to two processes: diffusion and advection. Diffusion is considered to be the principal mechanism in the interchange of gases between the soil and the atmosphere, although advection may be responsible for moving significant amounts of gas but generally over short time periods. The interchange due to diffusion results from concentration gradients established within soil by respiration of microorganisms, macrofauna, and plant roots; by production of gases associated with biological reactions, such as fermentation, nitrification, and denitrification; and by incorporation of chemicals, such as fumigants, anhydrous ammonia, pesticides, and volatile organic compounds (VOCs) from toxic waste sites. The diffusion of water vapor within the soil also occurs due to differences in vapor pressure gradients induced by temperature differences or by evaporative conditions at the soil surface.

Whereas diffusion is driven by concentration gradients, advection is driven by pressure gradients. Pressure gradients may develop due to barometric pressure changes in the atmosphere; wind blowing across the soil surface or against

a hill or other landscape feature; infiltration of water into the soil due to rainfall or irrigation; soil-water redistribution and evaporation; temperature gradients near the soil surface; and differences in gas density due to high concentrations of gases that have densities greater than air. Soil-gas pressure gradients are also created artificially using soil venting, or soil-vapor extraction, as techniques for removing harmful volatile gases from contaminated waste sites in the unsaturated zone (Rathfelder et al., 1995).

8.2 Soil-Air Composition

The composition of soil air depends on the relative magnitude of both the sources and sinks of the various gas components, the interchange between soil air and atmospheric air, and the partitioning of the gases between the gaseous, liquid, and solid (mineral and organic matter) phases of the soil. If a soil were completely "aerated," the concentrations of the gases in the soil air would be similar to that in the atmosphere. Oxygen concentrations in the soil air will be somewhat below that in the atmosphere (approximately 20% by volume), since O_2 is consumed in soil by plant root and microbial respiration (including soil mezofauna) and through chemical reactions. Under some conditions, O_2 concentrations can go to zero and the soil becomes anaerobic (anoxic). It is now widely accepted that under some conditions soil profiles do not have to be either fully aerated or fully anaerobic but may be partially aerobic and partially anaerobic. Anaerobic pockets or "hot spots" may exist within the soil due to pockets of very high O_2 consumption such as around incorporated carbon materials and/or due to very slow diffusion to regions of O_2 consumption. For example, the interior of large aggregates may be anaerobic due to slow diffusion to microbial "hot spots."

Carbon dioxide concentrations in the soil air can be as high as 10 times larger than in the atmosphere (0.036% by volume). Since nitrogen gas (N_2) is more abundant than other gases in the atmosphere (~76%) and there are generally no sources or sinks for N_2 in the soil (except N_2 produced during denitrification), the concentration of N_2 in the soil air will be similar to that in the atmosphere, varying only slightly depending on the production and consumption of other soil gases. The soil air will also contain varying amounts of nitric oxide and nitrous oxide (from nitrification and denitrification); methane, hydrogen sulfide, and ethylene (from anaerobic processes); water vapor; and trace amounts of inert gases such as argon. Human activities also result in the accidental or intentional introduction of gases in the soil profile such as fumigants, anhydrous ammonia, pesticides, and various organic chemicals that exist partially in the gas phase.

The concentrations of O_2 and CO_2 that occur in the soil-pore space vary widely, especially for CO_2, and depend on the rate of consumption and production and upon the rate that the soil is able to exchange these gases between the soil and the atmosphere through diffusion and advection. The diurnal and annual variability in the soil-gas concentrations is generally much greater

for clayey soils than for sandy soils due to the ability of sandy soils to transmit gases at a higher rate (larger soil-gas diffusion coefficients and air permeability) and maintain more constant concentrations.

8.3 Mechanisms of Gas Transport

8.3.1 Diffusion Processes and Definitions

The molecular transport of one gas relative to another is known as diffusion. Diffusion in porous media consists of several kinds of movement: *ordinary* or continuum diffusion (also known as molecular, mass, or concentration diffusion); *Knudsen* diffusion and *configurational* diffusion (free-molecule diffusion; Ho and Webb, 2006); *pressure* diffusion; *thermal* diffusion; *forced* diffusion; and *surface* diffusion. For the first of these, *ordinary diffusion*, molecules of a given species transfer momentum to the molecules of other species, and if a concentration or mole fraction gradient exists, there will be a net movement of a gas species from the more-concentrated region to the less-concentrated region. The probability of molecule–molecule collisions is much greater than molecule-wall collisions or, in other words, the distance that a molecule moves before it collides with another molecule (i.e., the mean free path), is much smaller than the soil-pore diameter.

For *Knudsen diffusion*, the probability of molecule–molecule collisions is negligible compared to molecule-wall collisions, or in other words, the mean free path is much larger than the soil-pore diameter. In this case, gas molecules transfer momentum predominately to the pore walls rather than to other gas molecules. The driving force for flow is due to a concentration gradient just as in ordinary diffusion. As the pore size gets even smaller, approaching that of single gas molecules, the flow mechanism changes and *configurational diffusion* (Ho and Webb, 2006) becomes important.

Pressure diffusion is the separation of gases of different molecular weight under a pressure gradient (Chapman and Cowling, 1970). Pressure diffusion causes the heavier molecules to diffuse toward the regions of greater pressures. Under the natural gravitational pressure gradient, the heavier molecules tend to diffuse downward along the direction of gravity. Pressure diffusion is generally negligible for vadose zone depths of less than 100 m (Amali and Rolston, 1993).

Thermal diffusion is the movement of gases due to a temperature gradient. This process appears to be minimal (Grew and Ibbs, 1952; Bird et al., 2007) because it requires large temperature gradients of 200°C or more, which are not possible under normal conditions in soils. Another diffusion process due to external forces such as a gravitational, electric, or magnetic field of some kind is called *forced diffusion*. For a case where gas molecules are adsorbed by a pore wall or surface, the gas molecule may migrate along the surface giving rise to *surface diffusion* where the binding energy is not too great. Since soil particles are generally covered by multiple layers of water, surface diffusion is either not likely or becomes incorporated into an

effective diffusion coefficient. For diffusion in soil and vadose zone materials, only ordinary and Knudsen diffusion are generally considered to be of most importance (Thorstenson and Pollock, 1989a, 1989b).

8.3.2 Gas Flux Definitions

As with diffusion processes, there are several different kinds of fluxes that arise from different driving forces in soils.

8.3.2.1 Ordinary Diffusive Flux

As mentioned earlier, ordinary or molecular diffusion occurs where there are no temperature or pressure gradients in systems where the pore size is much larger than the mean free path of the gas molecules or is dominated by molecule–molecule collisions. Although gas molecules are constantly in motion, there will only be a net flux (mass of gas moving across a cross-sectional area of soil per unit time) of a gas if a concentration or mole fraction gradient exists. Strictly speaking, ordinary diffusive flux only occurs for a binary mixture of gases that are of equal or nearly equal molecular weights, which results in equal countercurrent diffusion. Diffusion is considered to be "segregative" because the diffusing species has a different velocity than that of the gas as a whole (Cunningham and Williams, 1980).

For a two-component system consisting of gases i and j, the diffusive flux of gas i is given by Fick's first law,

$$N_i^F = -D_{ij}C\nabla y_i, \tag{8.1}$$

where

  N_i^F is the molar diffusive flux of gas i (mol m^{-2} s^{-1})
  C is the total molar density (mol m^{-3})
  D_{ij} is binary diffusion coefficient (m^2 s^{-1}) for the gas pair
  ∇y_i is the gradient in the mole fraction of gas i

Discussion of how Fick's law is adapted for use in porous media will be presented later.

8.3.2.2 Viscous Flux (Advection)

The flow of gas due to a pressure gradient is called viscous or advective flux. Viscous flux differs from that of diffusive flux in that the gas molecules lose momentum due to collisions with pore walls and there is no segregation of species since a specific gas species is moving at the same velocity as the gas as a whole (Cunningham and Williams, 1980). For soils, a viscous flux is due to the presence of a pressure gradient that arises from artificially applying a pressure difference in the soil or to such effects as barometric pressure changes, wind, and/or infiltration of water.

8.3.2.3 Nonequimolar Flux (Diffusion Slip Flux)

In general, ordinary diffusion of gases with equal molecular weights and equal countercurrent diffusion is rare in porous media.

The more common case is that diffusing gases differ in their molecular weights. If one considers two different gases of differing molecular weight initially separated that are allowed to diffuse into each other, two inseparable phenomena will occur. First, the lighter molecules will diffuse faster than the heavier molecules creating a higher concentration in the region toward which they flow. A pressure gradient thus develops that creates a nonsegregative viscous flux in a direction opposite to that of the direction of diffusion of the lighter molecules. Since this nonsegregative viscous flux arises as a result of a difference in concentration (nonequimolarity) it is called a "nonequimolar flux" (Cunningham and Williams, 1980). This flux is also called "diffusion slip flux." At some point, a quasi steady state will be reached, and the pressure gradient will become constant. Macroscopically, the only observable phenomena would be the equal and opposite net fluxes of the two different gases (Thorstenson and Pollock, 1989a, 1989b).

8.3.2.4 Knudsen Diffusive Flux

Knudsen diffusive or free-molecule flux occurs when the gas mean free path is much greater than the pore size. For this case, the gas molecules will collide only with the walls and rebounding molecules do not collide with other gas molecules. The flux is in response to a concentration gradient, there will be segregation of species, and specific species fluxes will be independent of one another and additive.

The Knudsen flux in a capillary tube can be described by

$$N_i^k = -D_i^k C\nabla y_i, \tag{8.2}$$

where

  N_i^k is the molar Knudsen flux of gas i (mol m^{-2} s^{-1})
  C is the total molar density (mol m^{-3})
  D_i^k is Knudsen diffusion coefficient (m^2 s^{-1}) for the gas i within the capillary tube
  ∇y_i is the gradient in the mole fraction of gas i (Reinecke and Sleep, 2002)

For unsaturated soils, a whole range of air-filled pore sizes will be available, and some method is needed to obtain an effective D_i^k for the porous medium. An approach used by Reinecke and Sleep (2002) is to make use of the Brooks–Corey equation relating soil-water potential to water-phase saturation (Corey, 1994). Using the Brooks–Corey relationship gives

$$D_i^k = D_i^{k0}(1 - S_e)^2(1 - S_e^{(1+\lambda)/\lambda}), \tag{8.3}$$

where

  D_i^{k0} is the Knudsen diffusion coefficient for an effective water saturation of zero (determined empirically)
  S_e is the effective water saturation
  λ is an empirical parameter called the pore-size distribution index that is determined from the soil-water characteristic for a particular soil or porous medium

8.3.2.5 Total Flux

The total molar diffusive flux, N_i^D, is the sum of the segregative ordinary diffusive flux and the nonsegregative nonequimolar diffusive flux given by

$$N_i^D = N_i^F + x_i \sum_{j=1}^{v} N_j^D, \qquad (8.4)$$

where $x_i \bullet \sum_{j=1}^{v} N_j^D$ is the nonequimolar flux.

The total molar gas flux is the sum of the total diffusive flux and the molar viscous flux given by

$$N_i^T = N_i^D + N_i^V. \qquad (8.5)$$

The equations for molar viscous flux will be given in a later section.

8.3.2.6 Diffusion versus Dispersion

According to the equation for total flux (Equation 8.5) above, the diffusive and the viscous flux are totally additive. However, it has been shown (Rolston et al., 1969) that when a pressure gradient is applied to soil columns inducing both viscous and diffusive flow that an additional gas mixing phenomena occurs called dispersion. Dispersion is a complicated phenomenon due to differences in gas velocities within a soil pore and between pores. Dispersion is usually handled mathematically by adding a dispersive flux term to the total advective or viscous flux (Jury and Horton, 2004). The dispersive flux is usually described by an equation identical to Fick's law, except the ordinary diffusion coefficient is replaced with a dispersion coefficient.

8.3.3 Gas/Liquid/Solid Partitioning

During gas transport through soils and vadose zone materials, some of the moving gas will dissolve in the soil water and some will adsorb onto soil surfaces. For oven-dry soil (no or little water adsorbed on soil surfaces), soils have a high capacity to adsorb gas. For example, Petersen et al. (1994, 1995) determined that the adsorption of toluene and trichloroethylene was 4 orders of magnitude higher on oven-dry soil than on moist soil. Water is preferentially adsorbed on soil surfaces over most soil gases, so for a moist soil, little gas will be adsorbed or partitioned on soil solids, but will be dissolved in soil water. The partitioning of soil gas between the solid and liquid phases is given by

$$C_s = K_d C_l, \qquad (8.6)$$

where

C_s is the mass concentration of adsorbed gas on the soil solids
K_d is the liquid/solid partitioning coefficient
C_l is the mass gas concentration in the liquid phase

The partitioning of soil gas between the gas and liquid phases is given by Henry's law,

$$C_g = K_H C_l, \qquad (8.7)$$

where

C_g is mass concentration of gas in the gas phase
K_H is the Henry's law constant

Soil gases vary significantly in their solubility in water. A table giving Henry's law constants for various soil gases and chemicals is given by Farrell et al. (2002).

8.3.4 Gas Reactions

8.3.4.1 Respiration

Oxygen is continuously consumed and CO_2 produced by plant roots and by soil microorganisms and other soil fauna. This process and the exchange of O_2 and CO_2 between soil and the atmosphere are called aeration. For a thorough description of soil aeration processes, see the texts of Glinski and Stepniewski (1985) and Scott (2000). The rates of O_2 consumption and CO_2 production are directly related to the rate of plant and microbial growth, which in turn is related to several environmental factors including air and soil temperature, substrate availability, and soil moisture. Many studies have shown that the bulk of the soil respiratory activity (>90%) occurs in regions of high organic matter near the soil surface (Glinski and Stepniewski, 1985). For aerobic conditions, the amount of CO_2 produced and O_2 consumed tends to be about equal. For anaerobic conditions, the CO_2 production will tend to be larger than the O_2 consumption because other reactions are occurring.

8.3.4.2 Oxidation/Reduction

These processes are connected with the transfer of electrons from soil organic matter (or organic contaminants) to oxidized inorganic compounds catalyzed by enzymes produced by soil microorganisms. For well-aerated conditions (aerobic), O_2 is the electron acceptor. When O_2 becomes limiting (anaerobic), other substances will accept electrons or be reduced. Examples of compounds that can be reduced under anaerobic conditions are nitrate, manganic manganese, ferric iron, sulfate, and perchlorate (a natural and anthropogenic contaminant). The reduction of nitrate and sulfate results in N_2 (and N_2O) and hydrogen sulfide gases, respectively. Another gas produced from reduction processes is methane (CH_4). Both CH_4 and N_2O are strong greenhouse gases and contribute to global warming. For further information on oxidation/reduction processes in soils, see Glinski and Stepniewski (1985).

8.3.4.3 Production and Consumption

There are a few gases produced in soils that are not necessarily associated with oxidation/reduction reactions. When fertilizer materials such as urea and ammonium salts are applied to the soil, reactions can occur, particularly in soils with a pH greater than

about 7.5 or 8 that produces ammonia gas (NH_3). Fairly large emission of NH_3 can occur, for instance, if urea is applied to the soil surface since urea hydrolysis results in a large increase in pH near the fertilizer granules, with NH_3 being emitted. The deeper the material is placed, the lesser the NH_3 will be emitted. Ammonia may also be produced in soil from the incorporation of animal waste.

Under aerobic conditions, ammonium-based materials either from fertilizer or mineralization of organic materials will be oxidized to nitrite and then to nitrate by microbial processes (nitrification). During nitrification, some N_2O and nitric oxide (NO) can be produced and emitted to the atmosphere (Venterea and Rolston, 2000). Nitric oxide enters into the tropospheric ozone cycle and can contribute to very small particle (<10 or <5 μm) generation in the atmosphere.

Besides O_2, gases including hydrocarbons, N_2O, NO, CH_4, and some sulfur gases may move from the atmosphere into the soil and be consumed by biological processes. Thus, the soil may act as a significant sink for atmospheric gases under some circumstances. At toxic waste sites, the vapors of VOCs may be prevalent in the gas phase of soil and may undergo various consumption and production processes. In other cases, fumigants, herbicides, and pesticides are added to soil for agricultural purposes, and the vapors of these chemicals may undergo consumption processes due to biodegradation.

8.4 Gas Transport Theory

8.4.1 Stefan–Maxwell Equations

In general, the diffusion velocities of gas mixtures in porous media are related to each other in a complex manner dependent upon the mole fraction of each gas, the molar fluxes of each gas, and the binary diffusion coefficient of each gas pair. Bird et al. (2007) indicate that the Stefan–Maxwell equations are simply an extension of Fick's law for multicomponent mixtures of gases. Curtiss and Hirschfelder (1949) gave the general equations for steady transport of a multicomponent mixture of gases, based on kinetic gas theory. If gravity effects are ignored or diffusion occurs only horizontally, the well-known Stefan–Maxwell equations provide the theoretical framework for 1D diffusion of gases in soils, given by

$$\sum_{j=1, i \neq j}^{n} \frac{y_j N_i - y_i N_j}{D_{ij}} = -\frac{P}{RT} \frac{dy_i}{dz}, \qquad (8.8)$$

where
- y_i and y_j are the mole fractions of gases i and j, respectively
- N_i and N_j are the molar fluxes (mol m^{-2} s^{-1}) of gas i and j, respectively
- D_{ij} is the binary diffusion coefficient (m^2 s^{-1}) for gas pairs i and j in the gas phase (no porous media)
- P is total pressure (kPa)
- R is the universal gas constant (m^3 kPa mol^{-1} K^{-1})
- T is absolute temperature (K)
- z is a spatial coordinate (m)

This equation results in n − 1 independent equations because

$$\sum_{i=1}^{n} y_i = 1. \qquad (8.9)$$

To use this equation for soils, the binary diffusion coefficient, D_{ij}, would need to be replaced with the soil-gas diffusion coefficient to be discussed later.

8.4.2 Fick's Equations

Fick's first law applies to steady-state gas transport, and Fick's second law is for unsteady (transient) transport derived by incorporating Fick's first law into the mass conservation equation. Fick's first law for diffusion is considered to be a restrictive case of the Stefan–Maxwell equations. Jaynes and Rogowski (1983) showed that Fick's law would result in incorrect estimations of mass distributions and fluxes for systems containing two or more vapor components when the concentrations of the diffusing species are not small compared to the bulk gas. They showed that in ternary systems, the Fickian diffusion coefficient depends not only on the binary diffusion coefficient and flux ratios but also on the mole fraction of the diffusing species. Leffelaar (1987) found that when the binary diffusion coefficients are different by a factor of two, the diffusion of gases in multicomponent gas mixtures could not accurately be described with Fick's law. Amali and Rolston (1993) showed that if the total mole fraction of VOC vapors in air exceeded about 0.05, Fick's law fluxes deviated from the true diffusive flux for each species by up to 5%. This indicated that the total mole fraction of the diffusing species also needs to be considered in addition to the requirement of Leffelaar (1987) that the binary diffusion coefficients of the diffusing species must be sufficiently different for multicomponent effects to be observed.

Thus, Fick's law is generally applicable for only a few special situations. One of these cases is for the diffusion of a trace gas in a binary mixture, meaning that the mole fraction of the tracer gas is small. The second special case is for diffusion of two gases in a closed system (total pressure remains constant or there is equimolar countercurrent diffusion). In this case, neither gas needs to be in trace amounts. A third case where Fick's law is applicable is for a three-gas system where there is equimolar, countercurrent diffusion of two of the gases and the third gas is stagnant (Jaynes and Rogowski, 1983). The consequences and potential errors of using Fick's law for situations other than the few special cases above are discussed in the application sections later on.

To use Fick's law for describing steady transport of a single gas species in soils, one must assume that the above conditions are met. Fick's first law given in mass fluxes and mass concentrations is

$$\frac{M_g}{At} = f_g^F = -D_p \frac{\partial C_g}{\partial z}, \qquad (8.10)$$

where

M$_g$ is the amount of gas diffusing (g gas)

A is the cross-sectional area of the soil (m^2 soil)

t is time (s)

f$_g^F$ is the gas flux density (g gas m^{-2} soil s^{-1})

C$_g$ is concentration in the gaseous phase (g gas m^{-3} soil air)

z is distance (m soil)

D$_p$ is the soil-gas diffusion coefficient (m^3 soil air m^{-1} soil s^{-1})

Soil air is considered to consist of a mixture of gases (i.e., N$_2$, O$_2$, CO$_2$, etc.). For unsteady transport of gases in soil, Fick's second law, including partitioning of the soil gas in soil water and onto soil surfaces and a source/sink term for production/consumption processes, is

$$R\varepsilon \frac{\partial C_g}{\partial t} = D_p \frac{\partial^2 C_g}{\partial z^2} - r_g, \qquad (8.11)$$

where R is the retardation factor given by

$$R = 1 + \frac{\theta}{\varepsilon K_H} + \frac{\rho_b K_d}{\varepsilon K_H} \qquad (8.12)$$

ε is the soil-air content (air-filled porosity; m^3 air m^{-3} soil)

r$_g$ is the sink or source (positive sign) that can be described by various kinetic equations

θ is soil-water content (m^3 water m^{-3} soil)

ρ$_b$ is soil dry bulk density (kg soil m^{-3} soil)

8.4.3 Dusty Gas Model

In order to use either the Stefan–Maxwell equations or Fick's law as given above to calculate soil-gas flux and/or concentration distributions, the equations are modified by inserting empirically obtained, soil-gas diffusion coefficients for the binary diffusion coefficients in free air (no porous media). Even without imposed pressure gradients in the soil, advective or viscous flow may occur in nonequimolar diffusion processes (discussed above). Only for equimolar gases will diffusion not result in advection. The phenomena of an advective flux due to diffusion of a non-equimolar system of gases have been implicitly included in the diffusion formulation (Bird et al., 2007), in that diffusion is in relation to the molar-average velocity of the gas as a whole (Ho and Webb, 2006). Coupling of diffusion and advection due to the nonequimolar phenomenon has been formulated with the development of the dusty gas model (DGM) by Mason et al. (1967). The DGM includes the effect of the porous media as a "dusty gas" component of the gas mixture, where the "dusty gas" is assumed to be large molecules fixed in space. The DGM combines ordinary and Knudsen diffusion through kinetic arguments and advective fluxes are added based on Chapman–Enskog kinetic

theory (Ho and Webb, 2006). Writing the DGM in terms of total molar flux (diffusive plus advective) relative to fixed coordinates (Thorstenson and Pollock, 1989a) gives

$$\sum_{\substack{j=1 \\ j \ne i}}^{n} \frac{y_i N_j^T - y_j N_i^T}{D_{ij}^e} - \frac{N_i^T}{D_i^k} = \frac{P\nabla y_i}{RT} + \left(1 + \frac{k_g P}{D_i^k \mu_g}\right)\frac{y_i \nabla P}{RT}, \qquad (8.13)$$

where

N$_j^T$ is the total molar flux of gas species j

D$_{ij}^e$ is the effective ordinary diffusion coefficient of gas species j in i

k$_g$ is the air permeability

μ$_g$ is the gas viscosity

The effective ordinary diffusion coefficient, D$_{ij}^e$, is equivalent to the soil-gas diffusion coefficient, D$_p$, in Fick's equations above. The first term on the left-hand side of the above equation considers molecule–molecule interactions and is recognized as the Stefan–Maxwell equations. The second term on the left-hand side takes into account molecule–particle interactions (Knudsen diffusion). The first and second terms on the right-hand side represent the driving forces for diffusion and advection due to gradients in gas partial pressure (concentration) and total pressure, respectively (Ho and Webb, 2006). If Knudsen diffusion is negligible and there are no total pressure gradients, the DGM simplifies to the Stefan–Maxwell equations. For a more thorough description of the DGM, see the books by Mason and Malinauskas (1983) and Ho and Webb (2006), and the papers by Thorstenson and Pollock (1989a, 1989b).

8.4.4 Darcy's Equation

Darcy's law can be used to describe advective gas transport in soils. For a nonreactive gas, the total molar advective (viscous) flux is given by

$$N^V = -\frac{P}{RT}\frac{k_g}{\mu_g}\nabla P. \qquad (8.14)$$

8.4.5 Convection–Dispersion Equation

If one assumes that for both diffusion and advection that the two processes are simply additive, then the total mass flux is the sum of the flux due to diffusion by Fick's law and that due to advection by Darcy's equation. Thus, the total mass flux is

$$f_g^T = f_g^F + f_g^D, \qquad (8.15)$$

where

f$_g^F$ is the mass flux due to Fick's first law

f$_g^D$ is the mass flux due to Darcy's equation

Combining these fluxes and the mass conservation equation (equation of continuity) and assuming that the gas is nonreactive gives

$$\frac{\partial C_g}{\partial t} = \frac{D_P}{\varepsilon} \frac{\partial^2 C_g}{\partial z^2} - \frac{f_g^D}{\varepsilon} \frac{\partial C_g}{\partial z}. \tag{8.16}$$

The term f_g^D/ε is the "average" velocity of gas $\overline{v}_g$ within pores. Due to additional mixing from dispersion (see definition above), the term $D_p/\varepsilon = D_H$ becomes somewhat of a fitting parameter and is called the dispersion coefficient (Rolston et al., 1969).

8.5 Measuring Gas Transport Parameters

8.5.1 Soil-Gas Diffusion Coefficient

In order to use the models above for calculating soil-gas fluxes and/or soil-gas concentration distributions, the fundamental parameter that must be determined either by measurement or from predictive equations is the soil-gas diffusion coefficient, D_P. Field or in situ methods are available, but the most common approach is a laboratory method using either undisturbed or repacked soil cores (Rolston and Moldrup, 2002). As with most other soil properties, the soil-gas diffusion coefficient is spatially variable, so multiple cores should be collected from each soil depth of interest. The diffusion coefficient is also strongly dependent upon the soil-air content (air-filled porosity), which is dependent upon the soil-water content. Thus, diffusion coefficients should be measured over a range of soil-air contents.

The standard laboratory method is based upon establishing a tracer gas concentration, C_o, within a chamber (Figure 8.1). One end of a soil core at concentration C_s is placed in contact with the gas of the chamber. The other end of the soil core is maintained at concentration C_s, usually by exposing the core to the atmosphere. The gas of interest diffuses either into or out of the chamber depending upon the gas concentration C_o compared to that outside the core. The other gases making up the atmosphere will diffuse in an opposite direction to that of the gas of interest. The rate of change of concentration versus time in the chamber is related to the soil-gas diffusion coefficient.

The gases to be used in measuring the soil-gas diffusion coefficient should be selected with some care to be sure that Fick's law is valid. As discussed above, this means that the gas of interest should be in trace amounts or that the self-diffusion coefficients of the gases in the diffusion apparatus are similar. Also, the gas should be basically nonreactive in order to simplify the mathematical derivation. For example, a trace gas that has been used for this purpose is Freon diffusing into air. Freon is nonreactive and can be measured in trace amounts by gas chromatography (Rolston and Moldrup, 2002). Another common approach is to use oxygen in air as the gas of interest diffusing into nitrogen gas. The two gases, O_2 and N_2, make up 99% of atmospheric air and their molecular weights are similar, basically making
FIGURE 8.1 Schematic showing boundary and initial conditions used in the recommended laboratory method for determining the soil-gas diffusion coefficient. (Redrawn from Rolston, D.E., and P. Moldrup. 2002. Gas diffusivity, p. 1141–1158. *In* G.C. Topp and J.H. Dane (eds.) Methods of soil analysis, Part 4, Physical methods. SSSA, Madison, WI. With permission from Soil Science Society of America.)

up a binary mixture. Thus, the self-diffusion coefficients are very similar. The binary diffusion coefficient of O_2 diffusing into either air or N_2 is very similar to the self-diffusion coefficients of O_2 and N_2. Based upon these arguments, with O_2 as the tracer gas in measurements of the soil-gas diffusion coefficient and using Fick's law, using O_2 as the tracer gas appears to be a valid approach. Furthermore, Leffelaar (1987) indicated that if the binary diffusion coefficients do not differ by more than a factor of 2, then Fick's law should be valid. Since O_2 is potentially consumed in moist soil and CO_2 is produced by microbial respiration, an additional error may occur. However, since the diffusion measurements are taken over fairly short time periods of a few minutes to a few hours, it is assumed that the consumption of O_2 and production of CO_2 is small, and the error in using O_2 as the tracer gas is considered to be small (<1.5%) (Moldrup et al., 2000b).

The method described here is based on solutions to Fick's second law given by Currie (1960). Similar procedures have been used by several investigators (Rust et al., 1957; Gradwell, 1961; Shearer et al., 1966; Flühler, 1973; Schjønning, 1985; Resurreccion et al., 2008).

For unsteady diffusion of a gas that is nonreactive (physically, biologically, and chemically), Equation 8.11 can be simplified to give

$$\varepsilon \frac{\partial C_g}{\partial t} = D_P \frac{\partial^2 C_g}{\partial z^2}, \tag{8.17}$$

where ε is the soil-air content (m^3 air m^{-3} soil).

In developing Equation 8.11, it is assumed that the soil is uniform with respect to the diffusion coefficient and that ε is constant in space and time. Equation 8.17 may be solved subject to the boundary and initial conditions given in Figure 8.1. The solution (Carslaw and Jaeger, 1959, p. 128) for the relative concentration in the chamber C_r is

$$C_r = \frac{C_g - C_s}{C_o - C_s} = \sum_{n=1}^{\infty} \frac{2h \exp(-D_p \alpha_n^2 t/\varepsilon)}{L(\alpha_n^2 + h^2) + h}, \qquad (8.18)$$

where

C_g is the concentration in the chamber ($g\,m^{-3}$)

$h = \varepsilon/(a\varepsilon_c)$, ε_c is the air content of the chamber ($1.0\,m^3$ air m^{-3} chamber), a is the length of the chamber or the volume V, of the chamber per area A, of soil

α_n, with n = 1, 2,…, are the positive roots of

$$\alpha L \tan \alpha L = hL. \qquad (8.19)$$

At some time greater than zero, the terms for $n \geq 2$ are negligible with respect to the first term, and Equation 8.18 reduces to

$$C_r = \frac{2h \exp(-D_p \alpha_1^2 t/\varepsilon)}{L(\alpha_1^2 + h^2) + h}, \qquad (8.20)$$

where α_1 is the first root of Equation 8.19 above. Thus, for a plot of $\ln C_r$ versus time t, Equation 8.20 becomes linear with the slope $= -D_p \alpha_1^2/\varepsilon$ for sufficiently large t.

To make the diffusion coefficient measurement, the diffusion apparatus is set up according to the boundary and initial conditions of Figure 8.1 using a diffusion chamber setup similar to Figure 8.2. The tracer gas is measured within the diffusion chamber initially and then at several times after tracer gas is allowed to diffuse either into or out of the diffusion chamber. Graph ln
FIGURE 8.2 Schematic diagram of a diffusion apparatus that uses oxygen as the tracer gas.

C_r versus time, t, according to Equation 8.20, and determine the slope $= -D_p \alpha_1^2/\varepsilon$ from the linear part of the curve. To get D_p from this relationship, one must have a measured value of ε, and the value of α_1 must be determined from Table 8.1. For specifics on the diffusion apparatus, measurement methodologies, and alternative approaches for handling the data, see Rolston and Moldrup (2002). Also, see Rolston and Moldrup (2002) for a description of some field methods for measuring D_p.

8.5.2 Air Permeability

The fundamental soil property for advective gas transport in soils is the air permeability. It is similar to hydraulic conductivity for soil water but differs in that the air permeability of dry porous media is larger than the corresponding permeability determined from water flow due to the occurrence of slip flux along the pore walls (Klinkenberg, 1941). As with the soil-gas diffusion coefficient, the air permeability differs for various soil types and is highly dependent upon soil-water content.

In principle, the air permeability is determined by imposing a pressure gradient across some volume of soil (a soil column in the simplest case) to induce a steady-state advective flow of gas through the soil. The steady-state approach is used predominately for laboratory methods where either the pressure gradient is maintained constant and the flow rate is measured or the flow rate is maintained constant and the pressure is measured. The pressure gradient across the column and the flow rate through the soil volume are measured and the air permeability is calculated from Darcy's equation (Equation 8.14).

There have been many experimental variations and measurement approaches of steady-state laboratory and field approaches since the early designs of Grover (1955) as discussed by Ball and
FIGURE 8.3 Schematic of a typical laboratory apparatus to measure the air permeability of a soil core.

Schjønning (2002). In a nonsteady-state field method first used by Kirkham (1946), air permeability was calculated from the rate of decrease in pressure in a tank supplying the air flowing through an in situ soil sample.

The laboratory technique recommended by Ball and Schjønning (2002) is the steady-state approach used by Ball et al. (1981) where the air permeability is measured on an intact or repacked soil core enclosed within a two-chamber apparatus. The two-chamber apparatus allows good control of the boundary conditions on each end of the soil core. For this technique, a constant flow of air is applied, and the pressure at each end of the soil core is accurately measured. For specifics on this technique, see Ball and Schjønning (2002). A typical apparatus is schematically shown by Figure 8.3.

The field method recommended by Ball and Schjønning (2002) is a steady-state, surface-chamber method where pressurized air is applied to a sharpened cylinder (recommended diameter and height of 200 mm) pressed into the soil. The top of the cylinder is sealed to create a closed chamber. Thus, air flows through the soil enclosed within the cylinder and flows out the bottom of the cylinder into the soil profile. Air flow rates and the pressure gradient across the cylinder of soil are measured precisely. Again, the air permeability is calculated from Darcy's law. This method is based on that of van Groenewoud (1968), Green and Fordham (1975), Liang et al. (1995), and Iversen et al. (2001). For specifics on this technique, see Ball and Schjønning (2002).

8.5.3 Dispersion Coefficient

The soil-gas dispersion coefficient is generally determined from laboratory soil column experiments (miscible displacement). An undisturbed or repacked soil column is set up with a system for pumping gas through columns, generally of differing soil-water content. The soil-air content for the column must be known. The flow rate of the gas is measured precisely, and a switching mechanism is established on the inflow end of the column so that the gas flow into the column can be switched from the background gas to the tracer gas. Initially, the column is flushed with a background gas such as N_2 until the flow becomes steady and the gas filled pores are completely filled with the background gas. Then, the inflow gas is switched to the tracer gas, and the concentration of the tracer gas is measured in the outlet gas stream. Some investigators have also measured the tracer gas concentration at various distances along the column in addition to the outlet gas stream. The concentration of the tracer gas in the outlet gas stream (and at sampling points along the column if applicable) is measured as a function of time, usually until the tracer gas concentration is equal to the concentration in the inflow stream. The inflow gas may be switched back to the background gas and tracer gas concentration in the outflow measured until the tracer gas approaches zero.

Solutions of the convective–dispersion equation (Equation 8.16) (Rolston et al., 1969; Costanza-Robinson and Brusseau, 2002, 2006) are then compared with the experimental data with the dispersion coefficient being a fitting parameter. Some investigators also curve fit the pore-gas velocity in the convective–dispersion equation (Hamamoto et al., 2009b) and then compare the fitted pore-gas velocity with the measured velocity determined from the gas flow rate and the soil-air content.

Various designs of the experimental apparatus have been used (Rolston et al., 1969; Costanza-Robinson and Brusseau, 2002; Poulsen et al., 2008), but Hamamoto et al. (2009b) constructed a unique apparatus that allows for the measurement of the soil-gas diffusion coefficient, the air permeability, and the dispersion coefficient on the same soil core shown schematically by Figure 8.4.

8.6 Predictive Equations

8.6.1 Soil-Gas Diffusion Coefficient

8.6.1.1 Repacked, Dry Soil

Prediction of the soil-gas diffusion coefficient (D_p) in dry porous media (void of water) normally can be described by the classical power law of Buckingham (1904),

$$\frac{D_P}{D_0} = A\varepsilon^B, \tag{8.21}$$

where

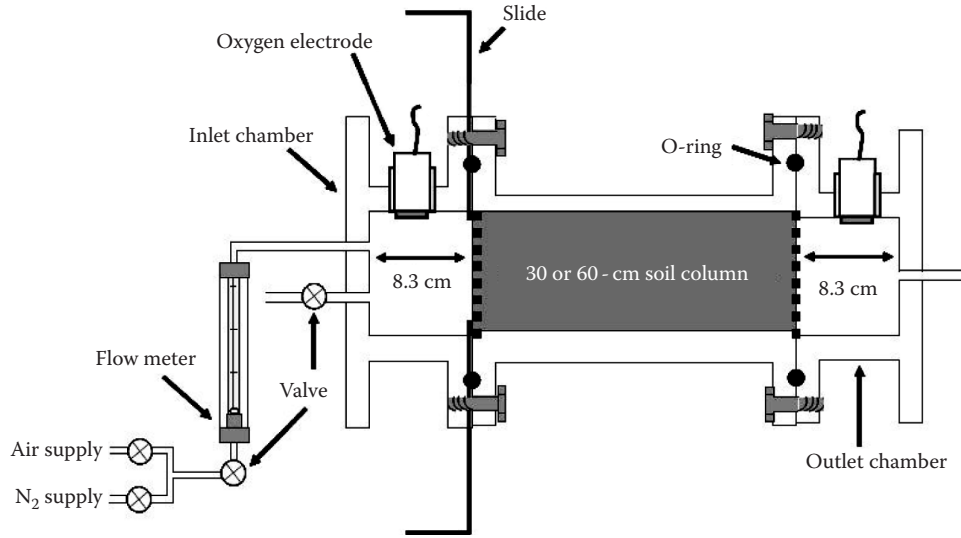
    D_P is the soil-gas diffusion coefficient (m^3 soil air m^{-1} soil s^{-1})
    D_0 is the gas diffusion coefficient in free air (m^2 air s^{-1})
    ε is the volumetric soil-air content (the air-filled porosity; m^3 soil air m^{-3} soil)
    A and B are empirical constants representing pore connectivity, continuity, and tortuosity of the dry porous medium


FIGURE 8.4 Schematic of a typical apparatus for measuring the dispersion coefficient of a soil core. Schematic simplified from unified measurement system (UMS) setup by Hamamoto et al. (2009b).

In the case of a dry porous medium, the soil-air content will equal the soil total porosity, Φ (m^3 pore space m^{-3} soil).

Moldrup et al. (2000b) tested three widely used models based on Equation 8.21: the Penman (1940) model (A = 0.66, B = 1), the Millington (1959) model (A = 1, B = 1.33), and the Marshall (1959) model (A = 1, B = 1.5). They found that all three models performed well against data for a wide range of sieved, repacked dry porous media (sand, soil, glass beads, steel and glass wool, and various mixtures) in the range of $0.2 < \Phi < 0.6$. The Marshall (1959) model,

$$\frac{D_p}{D_0} = \varepsilon^{1.5}, \tag{8.22}$$

performed best across the entire range of air-filled porosities and is generally recommended to predict the soil-gas diffusion coefficients in dry, nonaggregated soil.

In the case of aggregated soil with bimodal pore-size distribution, recent studies (Resurreccion et al., 2008, 2010) suggest that the change of D_p/D_0 with ε in the intraaggregate pore space is linear and often with a slope close to 0.5. Thus, if the soil is highly aggregated and with known values of interaggregate porosity (Φ_1; m^3 interaggregate pore space m^{-3} soil) and intraaggregate porosity ($\Phi_2 = \Phi - \Phi_1$), which could be determined from the measured soil-water retention curve (Resurreccion et al., 2009), the soil-gas diffusion coefficient for dry conditions may be estimated from

$$\frac{D_p(\varepsilon = \Phi)}{D_0} = (\Phi_1)^{1.5} + 0.5\Phi_2. \tag{8.23}$$

8.6.1.2 Repacked, Wet Soil

In the case of wet porous media, the soil water will typically be located in the narrow bottlenecks between pores, meaning a small amount of water can have a dramatic effect in reducing D_p/D_0 (Papendick and Runkles, 1965; Moldrup et al., 2000a). This is illustrated in Figure 8.5 for a sieved, repacked fine sand (Toyoura sand, Japan; data from Hamamoto et al., 2009a) at different moisture contents compared with dry
FIGURE 8.5 Prediction of the soil-gas diffusivity in dry and wet (variably saturated) sand. Models considered are the Millington (1959) and Marshall (1959) models for dry soil (void of water) and a WLR type of model for variably saturated soil (Moldrup et al., 2000b). (Data from Moldrup, P., T. Olesen, J. Gamst, P. Schjønning, T. Yamaguchi, and D.E. Rolston. 2000a. Predicting gas diffusivity in sieved, repacked soil: Water-induced linear reduction model. Soil Sci. Soc. Am. J. 64:1588–1594; Moldrup, P., T. Olesen, P. Schjønning, T. Yamaguchi, and D.E. Rolston. 2000b. Predicting the gas diffusion coefficient in undisturbed soil from soil water characteristics. Soil Sci. Soc. Am. J. 64:94–100; Hamamoto, S., P. Moldrup, K. Kawamoto, and T. Komatsu. 2009a. Effect of particle size and soil compaction on gas transport parameters in variably saturated, sandy soils. Vadose Zone J. 8:986–995.)

Toyoura sand and different other dry sands from the literature (data compiled by Moldrup et al., 2000a). In the dry state at different levels of compaction (open circles), the measured data are mostly placed in between the models by Millington (1959: A = 1 and B = 1.33 in Equation 8.21) and Marshall (1959, Equation 8.22). In the wet state at different moisture contents (filled-out circles), the D_p/D_0 is markedly reduced compared to the dry state at the same air-filled porosity. This leads to the development of the so-called water-induced linear reduction (WLR) class of models (Moldrup et al., 2000a; Hamamoto et al., 2009a), where the D_p/D_0 model for an equivalent dry media at a given ε (Equation 8.21) is multiplied with a water reduction factor,

$$F = \left(\frac{\varepsilon}{\Phi} \right)^N, \tag{8.24}$$

where N for repacked soils typically can be taken as 1 (Moldrup et al., 2000b; Hamamoto et al., 2009a; Resurreccion et al., 2009). If the Marshall (1959) model (Equation 8.22) is assumed at dry conditions and N = 1 is applied in Equation 8.24, the resulting WLR (Marshall) model becomes

$$\frac{D_p}{D_0} = \varepsilon^{1.5} \left(\frac{\varepsilon}{\Phi} \right). \tag{8.25}$$

This model with a high degree of accuracy predicted D_p/D_0 in sieved, repacked soil across the entire water content range from wet to dry, and with soil texture ranging from 0% to 54% clay (Moldrup et al., 2000a). Figure 8.6 shows the performance of the WLR (Marshall) model against data for 15 sands and differently textured soils from the literature (data compiled by Moldrup et al., 2000a and Hamamoto et al., 2009a), with total porosities (Φ) ranging from 0.4–0.5 m³ m⁻³ (average 0.45 m³ m⁻³). Also shown is the still most commonly used model in the literature for predicting gas diffusivity, the Millington and Quirk (1961) model,

$$\frac{D_p}{D_0} = \frac{\varepsilon^{3.33}}{F^2} = \varepsilon^{1.33} \left(\frac{\varepsilon}{\Phi} \right)^2. \tag{8.26}$$

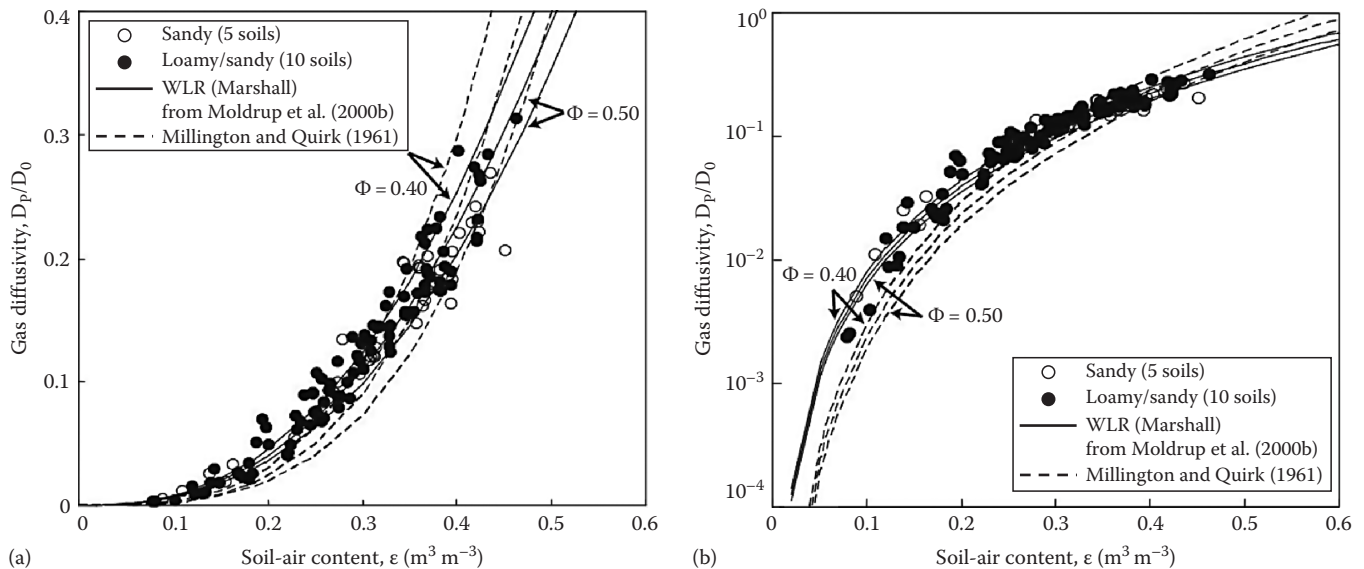
The Millington and Quirk (1961) model when rewritten like the right-hand side of Equation 8.26 is recognized as an analogue to the WLR model, here based on Millington (1959; A = 1 and B = 1.33) at dry conditions and with N = 2 in Equation 8.24, representing a nonlinear water reduction factor. Both at high gas diffusivities (see Figure 8.6a with normal-scale D_p/D_0 axis) and at low gas diffusivities (see Figure 8.6b with log-scale D_p/D_0 axis), the WLR model (Equation 8.25) is more accurate than the Millington and Quirk model (Equation 8.26). The upper, middle, and lower prediction curves for each model (WLR solid line, Millington and Quirk dotted line) in Figure 8.6a and b represent Φ = 0.4, 0.45, and 0.5 m³ m⁻³, respectively.


FIGURE 8.6 Prediction of the soil-gas diffusivity in variably saturated sands and soils with 0%–54% clay. Models considered are the widely used Millington and Quirk (1961) model (dotted line) and WLR model (Moldrup et al. 2000b; solid line). Model performance is shown in (a) normal-scale D_p/D_0 and (b) log-scale D_p/D_0 plots, and for values of soil total porosity (Φ) equal to 0.4 (upper line; representing minimum Φ for data), 0.45 (average for all data), and 0.5 (lower line; representing maximum Φ for data). (Data from Moldrup, P., T. Olesen, J. Gamst, P. Schjønning, T. Yamaguchi, and D.E. Rolston. 2000a. Predicting gas diffusivity in sieved, repacked soil: Water-induced linear reduction model. Soil Sci. Soc. Am. J. 64:1588–1594; Moldrup, P., T. Olesen, P. Schjønning, T. Yamaguchi, and D.E. Rolston. 2000b. Predicting the gas diffusion coefficient in undisturbed soil from soil water characteristics. Soil Sci. Soc. Am. J. 64:94–100; Hamamoto, S., P. Moldrup, K. Kawamoto, and T. Komatsu. 2009a. Effect of particle size and soil compaction on gas transport parameters in variably saturated, sandy soils. Vadose Zone J. 8:986–995.)

The reason why both measured data and predictive models suggest that the D_p/D_0 at a given air-filled porosity (ε) is larger at higher compaction (lower Φ) is due to the larger water to solid ratio, remembering that increasing water content typically has a dramatic effect on reducing air-filled pathways for gas diffusion, since water will form water blockages in bottlenecks between air-filled pores. For example, a soil with an air-filled porosity of $\varepsilon = 0.25\,m^3\,m^{-3}$ and a total porosity of $\Phi = 0.4\,m^3\,m^{-3}$ will contain a volumetric water content of $\theta = 0.15\,m^3\,H_2O\,m^{-3}$ soil and a volumetric solids content of $V_S = 0.6\,m^3$ solids m^{-3} soil. This yields a volumetric water/solids ratio, θ/V_S, of 0.25. If the same soil has a higher total porosity of $\Phi = 0.5$ (less compacted), the same ε as before will give a θ/V_S ratio of $0.25/0.5 = 0.5$ (double the ratio), which explains the markedly higher water blockage effects and smaller D_p/D_0 at larger Φ.

The Millington and Quirk (1961) model performs well in some cases. Equation 8.26 normally predicts D_p/D_0 well in uniform, coarse sandy soils (not included in Figure 8.6), since the water blockage effects will be more pronounced in media with larger particles and lower number of pores and bottlenecks between pores, explaining the sometimes higher N values for sandy media (Thorbjørn et al., 2008; Hamamoto et al., 2009a; Resurreccion et al., 2009).

It is further noted that in the case of aggregated soil (bimodal pore-size distribution), it will again be necessary to apply a two-region model, with the gas diffusivity (D_p/D_0) in the interaggregate pore space described by Equation 8.24 with Φ set equal to the interaggregate porosity Φ_1 (Jones et al., 2003) and $D_p(\varepsilon)/D_0$ in the intraaggregate pore space described by a linear relation (Resurreccion et al., 2009).

8.6.1.3 Undisturbed Soil

In the case of undisturbed soil, Werner et al. (2004) suggested that the WLR (Marshall) model, Equation 8.25, was the most accurate compared to a number of classical, soil-type independent models (including Equation 8.26) when tested against field-measured D_p/D_0 across soil types and moisture conditions. However, to some extent soil structure will influence gas diffusivity in undisturbed soil compared to sieved, repacked soil. Moldrup et al. (1999) therefore suggested using the Campbell pore-size distribution parameter b as a soil structure index for gas diffusivity. The Campbell b equals the negative slope of the soil-water retention curve in a pF (i.e., $\log -\psi$) versus $\log(\theta)$ plot, where ψ is soil-water matric potential in $cm\,H_2O$ and θ is volumetric soil-water content in $m^3\,H_2O\,m^{-3}$ soil (Campbell, 1974; Jury and Horton, 2004),

$$b = \frac{-d[\log(-\psi(\theta))]}{d[\log(\theta)]}, \tag{8.27}$$

where b will always be >0. The Campbell soil-water retention model normally performs best in the pF interval between 1.2 and 3.2. Moldrup et al. (1999) introduced and successfully tested a power law model for D_p/D_0 with the exponent equal to 2 + (3/b), following the capillary tube model for hydraulic conductivity by Burdine (1953),

$$\frac{D_p}{D_0} = \left(\frac{D_p^\star}{D_0} \right) \left(\frac{\varepsilon}{\varepsilon^\star} \right)^{2+(3/b)}, \tag{8.28}$$

where

$\varepsilon^\star$ is the air-filled porosity at $D_p = D_p^\star$

$D_p^\star$ is the soil-gas diffusion coefficient at a given reference-point soil-water content (e.g., zero water content equal to air saturation) or a given soil-water matric potential

At pF 2 ($-100\,cm\,H_2O$ of soil-water matric potential), where only the larger pores of $>30\,\mu m$ equivalent pore diameter are air filled, a good relation ($r^2 = 0.97$) between D_p/D_0 at pF 2 (D_{p100}/D_0) and air-filled porosity at pF 2 (ε_{100}) was found for 126 differently textured, undisturbed soils (Moldrup et al., 2000b),

$$\frac{D_{p100}}{D_0} = 2\varepsilon_{100}^3 + 0.04\varepsilon_{100}. \tag{8.29}$$

Using this as reference-point gas diffusivity in the Moldrup et al. (1999) b-dependent model yields for undisturbed, less-aggregated soil (Moldrup et al., 2000b):

$$\frac{D_p}{D_0} = (2\varepsilon_{100}^3 + 0.04\varepsilon_{100}) \left(\frac{\varepsilon}{\varepsilon^\star} \right)^{2+(3/b)}. \tag{8.30}$$

This macroporosity (ε_{100}) and b-dependent model well predicted gas diffusivity in differently textured, undisturbed soils across a wide range of soil and moisture conditions (Moldrup et al., 2000b, 2004; Rolston and Moldrup, 2002; Kawamoto et al., 2006b).

Recently, Moldrup et al. (2005) developed soil-gas diffusivity models for undisturbed soil linked to the van Genuchten (1980) soil-water retention model to establish a more direct and detailed link between pore-size distribution and soil-gas diffusivity. However, these models are presently more useful for description (curve-fitting to measured data) than prediction due to the combined high number of soil-water retention and pore tortuosity–connectivity parameters involved.

The above models represent only a few, although likely the most precise and useful currently, among the numerous predictive models available for soil-gas diffusivity. A more thorough listing and discussion of predictive and descriptive $D_p(\varepsilon)/D_0$ models can be found in Tick et al. (2007) and Allaire et al. (2008).

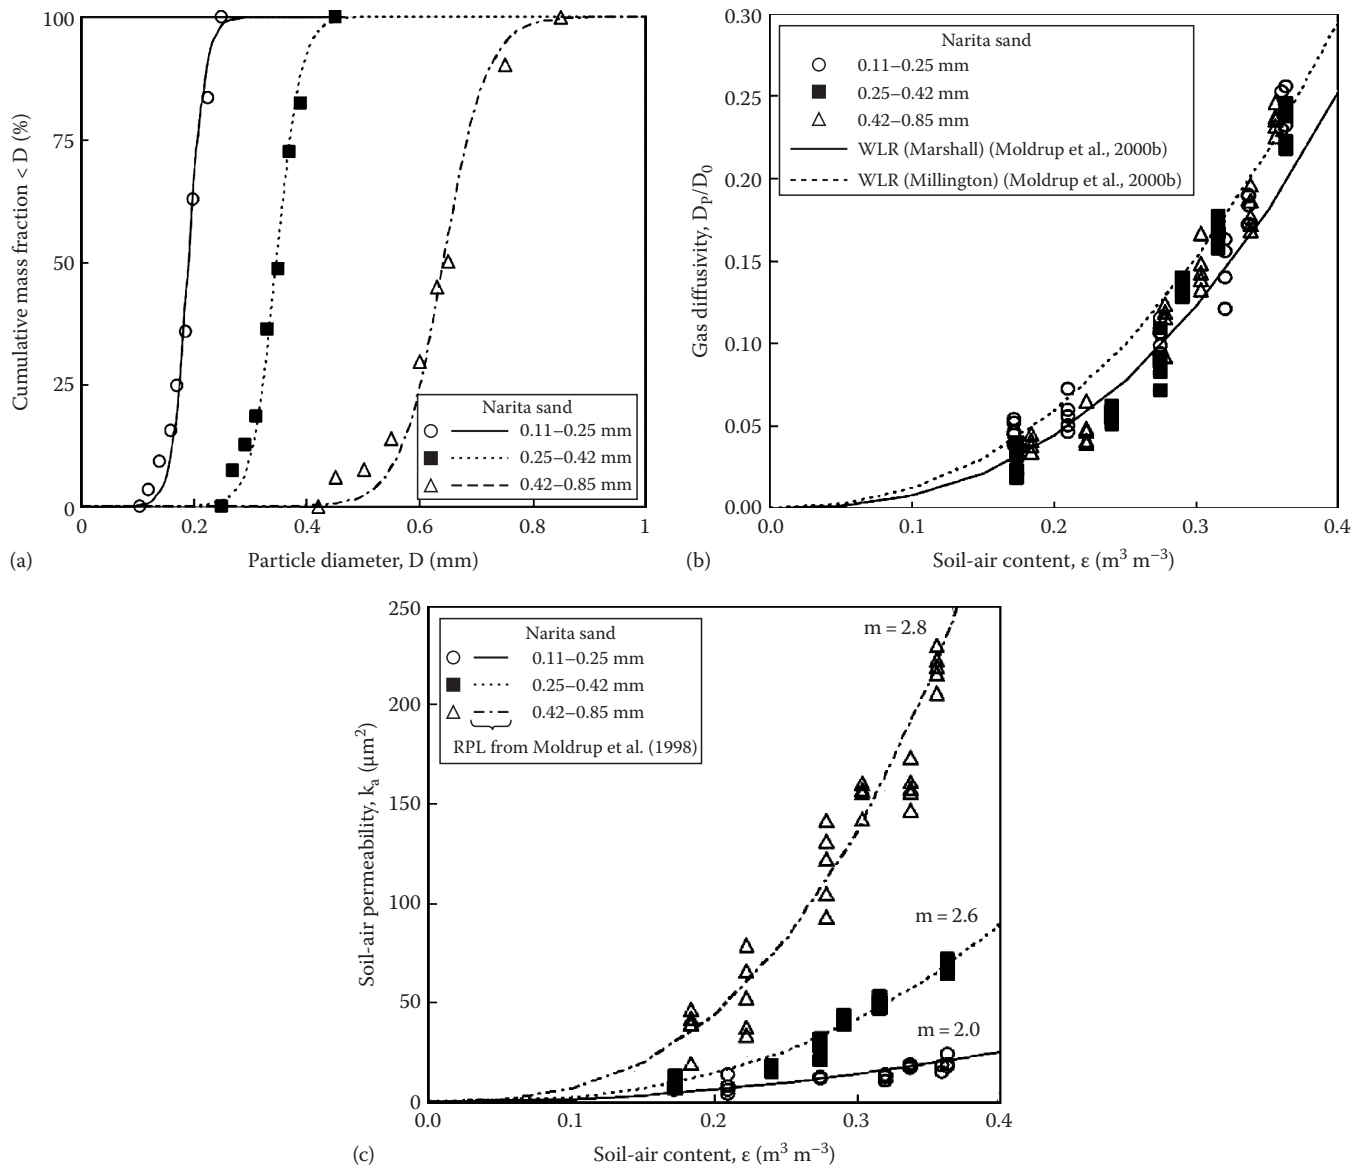
When using the predictive equations for relative gas diffusivity in simulation models for diffusive gas transport, the D_0 needs to be known for the actual gas under consideration at the given temperature. For example, the trace gas diffusion coefficient of oxygen in air at 20°C equals the trace gas diffusion coefficient of methane in air at 25°C, equal to $0.205\,cm^2\,s^{-1}$ (Andrussow and Schramm, 1969; Kruse et al., 1996). Further values for the binary diffusion coefficients of common gases at standard temperature and pressure are provided by Rolston and Moldrup (2002) that


FIGURE 8.7 Relation between basic soil physical properties and gas transport parameters for three size fractions of Narita sand. (a) particle-size distribution, (b) gas diffusivity, and (c) air permeability. Also shown are predictions by (b) the WLR type of D_P/D_0 models (Moldrup et al., 2000b), and (c) a general power law model for k_a (Moldrup et al., 1998). (Data from Hamamoto, S., P. Moldrup, K. Kawamoto, and T. Komatsu. 2009a. Effect of particle size and soil compaction on gas transport parameters in variably saturated, sandy soils. Vadose Zone J. 8:986–995.)

also provides references for additional gas mixtures and an equation (Fuller et al., 1966) to calculate D_0 for nonpolar gases from molar mass and volume, pressure, and temperature.

8.6.2 Air Permeability and Soil-Gas Dispersion Coefficient

Robust predictive models for air permeability (k_a) and the soil-gas dispersion coefficient (D_H) are presently not available across soil type and scale. Both convective gas transport parameters are highly sensitive to small changes in particle and pore-size distribution and soil structure. This is contrary to the behavior for gas diffusivity (D_P/D_0, previous section) where the influence

of pore-size distribution and soil structure is minor, especially for repacked soil (Moldrup et al., 2001). This is illustrated in Figure 8.7 for three different particle-size fractions of a sandy soil (Narita sand, Japan, data from Hamamoto et al., 2009a). The particle-size distribution of the three size fractions are shown in Figure 8.7a. Despite the differences in particle (and thus pore)-size distribution, the difference in measured gas diffusivity (D_P/D_0) curves between the three size fractions are minor, and the WLR model based on either Millington (1959) or Marshall (1959) at dry conditions and with $N = 1$ (Equation 8.25) well predict the data (Figure 8.7b). In contrast to this result, the effect of particle (and thus pore)-size distribution on air permeability, k_a (μm^2), is dramatic (Figure 8.7c).

8.6.2.1 Air Permeability

Moldrup et al. (1998, 2003) suggested a reference-point power law model for $k_a(\varepsilon)$, analogous to Equation 8.28 for D_p/D_0,

$$k_a = k_a^* \left(\frac{\varepsilon}{\varepsilon^*} \right)^m,$$
(8.31)

where

k_a is the soil-air permeability (μm^2)

ε^* is the volumetric soil-air content

k_a^* is the air permeability at a given reference point of moisture content or soil-water matric potential

m is a tortuosity–connectivity parameter for convective gas transport

If the reference point is again (like for soil-gas diffusivity, Equation 8.30) chosen at pF 2 (–100 cm H_2O), the $k_a(\varepsilon)$ model becomes

$$k_a = k_{a100} \left(\frac{\varepsilon}{\varepsilon_{100}} \right)^m.$$
(8.32)

For the three particle-size fractions in Figure 8.7c, both k_{a100} and m markedly increase with particle size and thus median air-filled pore size. Kawamoto et al. (2006a) developed a predictive equation for k_{a100} from ε_{100}, and D_{p100} (applying Equation 8.29 for D_{p100}) by combining Fick's law for diffusive transport with Poiseuille's law for convective fluid transport and assuming soil pores to be uniform, tortuous and nonjointed tubes of similar diameter to give

$$k_{a100} = \left(\frac{d_{100}^2}{32} \right) \frac{D_{p100}}{D_0} = \left(\frac{d_{100}^2}{32} \right) (2\varepsilon_{100}^3 + 0.04\varepsilon_{100})$$
(8.33)

where the average equivalent pore diameter for convective gas transport at pF 2 was found to be $d_{100} = 150\,\mu m$ (i.e., around five times the minimum drained pore size at pF 2), Inserting this in Equation 8.33 gives

$$k_{a100} = 700(2\varepsilon_{100}^3 + 0.04\varepsilon_{100}).$$
(8.34)

Kawamoto et al. (2006a) suggested an expression for the tortuosity–connectivity parameter for convective gas transport, m in Equation 8.32, based on the Alexander and Skaggs (1986) capillary tube model for unsaturated water permeability, m = 1 + (3/b), where b is the Campbell pore-size distribution parameter (Equation 8.27). Combining Equations 8.32 and 8.34 and inserting m = 1 + (3/b) yield

$$k_a = 700(2\varepsilon_{100}^3 + 0.04\varepsilon_{100}) \left(\frac{\varepsilon}{\varepsilon_{100}} \right)^{1+(3/b)}.$$
(8.35)

This $k_a(\varepsilon)$ model described well the air permeability for differently textured undisturbed soils (100 cm³ scale) sampled from two deep vadose zone profiles. If Campbell b is not known, average b values of 3 for sandy soils (m = 2), 6 for silty soils (m = 1.5), and 10 for clayey soils (m = 1.3) are recommended. For coarse porous media like the two largest particle-size fractions of Figure 8.7, m values significantly higher than 2 can be observed (Figure 8.7c), and the d_{100} value (Equation 8.33) likely exceeds $150\,\mu m$. Compared to soil-gas diffusivity, the prediction inaccuracy for k_a is high (order of magnitude) and likely highly scale dependent. It is again stressed that reliable models for k_a across soil types and scales are not available, and this parameter if possible should be measured in situ.

8.6.2.2 Dispersion Coefficient

The same lack of models are evident for the soil-gas dispersion coefficient, D_H (m² s⁻¹) where very limited amount of studies and measurements have been carried out since the first major study by Rolston et al. (1969). Like for gas diffusivity and air permeability, Hamamoto et al. (2009b) found different behavior and $D_H(\varepsilon)$ curve shapes for structureless (unimodal) and aggregated (bimodal) soils packed in 30 or 60 cm columns. They also for the first time documented quantitative links between the soil-gas diffusion coefficient, air (gas) permeability, and soil-gas dispersion coefficient for structureless soils and in the interaggregate region of aggregated soils. They found that the soil-gas dispersivity (λ, in m),

$$\lambda = \frac{D_H}{\bar{v}_g},$$
(8.36)

where $\bar{v}_g$ is the pore-gas velocity, was closely related to the soil-gas diffusion coefficient and air-filled porosity. The best-fit relation was

$$\lambda = 0.0185 \left(\left(\frac{\varepsilon D_0}{D_p} \right)^{0.5} - 1 \right).$$
(8.37)

Combining Equations 8.36 and 8.37 with the WLR (Marshall) model for D_p, Equation 8.25, yields

$$D_H = \bar{v}_g \times 0.0185 \left(\left(\frac{\Phi}{\varepsilon^{1.5}} \right)^{0.5} - 1 \right),$$
(8.38)

where

D_H is in m² s⁻¹

$\bar{v}_g$ in m s⁻¹

This relation needs further testing and modification against a wider range of soil types, for undisturbed soils, and at different

measurement scales. Presently, Equation 8.38 is therefore suggested to be used only as an order of magnitude estimate for D_H.

8.7 Applications

There have been many studies to evaluate the applicability of the various models and equations for simulating the movement of gases within porous media for a whole range of chemicals, porous media type, and applications. For soil science and other disciplines, the bulk of the applications have used Fick's laws for modeling purposes. However, as noted above, Fick's laws are only applicable under a limited set of conditions. From the results of multiple studies, some general statements can be made about the applicability of the various models for various modeling situations. For cases of multinary system of gases and where the diffusion coefficients of the diffusing gases are very much different from one another, the Stephan–Maxwell equations would be more appropriate than Fick's law. Neither Fick's law nor the Stephan–Maxwell equations consider Knudsen diffusion. Thus, for porous media with very small pores and with small air permeabilities where Knudsen diffusion may be important, both of these models may be inadequate to model gas transport. The dividing line between molecular and Knudsen diffusion is still quite uncertain, but there is some evidence that Knudsen diffusion becomes important and should be included in models for air permeability less than 10^{-13} m^2 (Sleep, 1998; Webb and Pruess, 2003). The air permeability for many natural soils at field-water content range from about 10^{-10} to 10^{-12} m^2, except for heavy clay soils (>20% clay), where the air permeability may be as low as 10^{-14} m^2 (Moldrup et al., 1998; Kawamoto et al., 2006a). Fick's law and the Stefan–Maxwell equations also may prove inadequate when nonequimolar fluxes result in large pressure gradients and subsequent large viscous fluxes. For porous media with small air permeability, the DGM is generally considered to be superior over the other models because it not only considers Knudsen diffusion but also is applicable to multinary mixtures of counter diffusing gases (Abriola and Pinder, 1985; Thorstenson and Pollock, 1989a, 1989b; Massmann and Farrier, 1992; Sleep, 1998; Webb, 2006).

For cases where either naturally occurring or imposed pressure gradients occur within porous media, both advection and diffusion are controlling processes of gas transport. For high permeability and low concentration of the gas of interest, it is generally considered that the convection–dispersion equation is adequate for modeling. However, if concentration of the gas of interest is high and nonequimolar fluxes may occur, the DGM (with an advective component added) may be more appropriate (Abu-El-Sha'r and Abriola, 1997). For nonisobaric (pressure gradients) conditions and low permeability, the DGM is needed and is generally considered to be superior over the convection–dispersion equation (Webb, 2006). There is still a debate about the applicability of the various models to real porous media, and there is still large uncertainty in the appropriate parameter values to use in the models.

8.7.1 Soil Aeration

As discussed above, soil aeration is generally considered to be the exchange of gases between the soil and the atmosphere, but more specifically, it is the transport of O_2 from the atmosphere to the soil microbial and root respiration sites and the exchange of generated CO_2 from the soil to the atmosphere. The ratio of the production of CO_2 (moles) to the consumption of O_2 (moles) is called the respiration quotient (Freijer and Leffelaar, 1996). The respiration quotient is determined by the C–H–O ratio and the fraction of the carbon sources that is mineralized to CO_2. The respiration quotient varies from 0.8 to 1.1 for most constituents of soil organic matter (Freijer et al., 1995).

Soil respiration is basically a ternary system of diffusion of N_2, O_2, and CO_2 (Argon neglected). Fick's first and second laws have often been used in an effort to quantify soil respiration from measurements of the concentration gradients of O_2 and CO_2 within soil profiles. For example, de Jong and Schappert (1972) used field-measured CO_2 gradients to calculate the flux of CO_2 in order to estimate soil respiration rates. Freijer and Leffelaar (1996) used the Stefan–Maxwell equations to evaluate soil respiration. They concluded that only using Fick's law for a fairly wide range of the respiration quotient and the O_2 consumption rate that the errors in the CO_2 gradients were small (<5%), but that the errors in the O_2 gradients were substantial. Freijer and Leffelaar (1996) showed through comparison of Fick's law with the Stefan–Maxwell calculations that there will be no error in the O_2 gradient only when the respiration quotient is close to 0.789. Thus, using Fick's law and the gradient of CO_2, as did de Jong and Schappert (1972), soil respiration rate may be estimated reasonably well, but errors will occur if the gradient of O_2 is used to calculate the flux. Leffelaar (1987, 1988) developed a method to correct the Fickian fluxes by considering the diffusive flux to consist of the Fickian component and a correction term to account for the effect of the presence of other gases (nonequimolar diffusion).

8.7.2 Greenhouse Gas Emissions

The three most prevalent greenhouse gases that may be emitted from soils are CO_2, N_2O, and CH_4. The most common methodology to quantify the emissions of these gases is to measure the surface flux by placing chambers over the soil surface. Transport in soil is not considered for this methodology except to correct the diffusion flux due to nonlinear behavior of the chamber concentration versus time curves (Livingston et al., 2006; Venterea and Baker, 2008). As for soil aeration, one could use Fick's law or some other theory to calculate the diffusion fluxes from measured concentration gradients within the soil near the soil surface. Since the greenhouse gases are generally in trace amounts in soil compared to the other soil gases, one may consider a binary system comprised of a trace gas diffusing into air (especially near the soil surface). Thus, the effective diffusion coefficient from Fick's law would be equal to the binary diffusion coefficient (Jaynes and Rogowski, 1983), and Fick's law could be

used to calculate the fluxes. However, the large spatial variability of greenhouse gas concentration profiles in soils generally makes this estimate of emission very uncertain.

8.7.3 Soil Fumigation

Various fumigants, including methyl bromide and 1, 3-dichloropropene, have been extensively used in agriculture to control soilborne pests such as nematodes. Fumigants are generally applied by shank injection into the soil and the soil surface often covered with some kind of plastic tarping material in an attempt to slow the transport of the gas from the soil to the atmosphere in order to attain effective control of the pests. Although some of the early models only considered diffusive transport using Fick's law (Rolston et al., 1982), the process of gas movement within the soil can be by both diffusion and advection (from the injection and volatilization process, wind, barometric pressure changes). A later model (Chen et al., 1995) used a modified convection–dispersion equation to model the transport of a fumigant with barometric pressure fluctuations. Wang et al. (1997, 2000, 2004) used a convection–dispersion model coupled to a heat, water, and transport model to evaluate the movement of fumigants in soils. Although Chen et al. (1995) indicate good agreement between model simulations and measurement of surface volatilization of the fumigant, this case of high concentration of fumigant, cotransport of water vapor (Leffelaar, 1987; Petersen et al., 1996), and advective transport due to pressure gradients may be a situation where the DGM could have been applied.

Model applications include simulating scenarios of injection depth and either plastic film or high soil-water content near the soil surface in order to attempt to decrease the flux of fumigant out of soil and into the atmosphere (Allaire et al., 2004). Potentially as equally important as using the most appropriate gas transport model is to use the most appropriate predictive equation for D_p. For example, the Millington and Quirk (1961) relation would underestimate the soil-gas diffusion coefficient at the higher water contents.

8.7.4 Volatile Organic Compounds and Vapor Extraction

In recent years, there has been a lot of interest in the movement of VOCs from contaminated soil sites to sites where humans may be exposed to these chemicals. Also, soil-vapor extraction has been used as a means to remediate contaminated sites by removing and treating the vapor phase (Falta, 2006). The transport mechanism for soil-vapor extraction is primarily advection, and Darcy's law has been extensively used (Falta, 2006). Many VOCs have molecular weights much different than air, and consequently their diffusion coefficients are much different than air. Also, the vapor concentration of these chemicals in soil can also be quite high especially near the contaminated soil or aquifer. Since some of the volatile chemicals are also being biodegraded in the subsurface, O_2 will be consumed and CO_2 produced, setting up a complex transport system of nonequimolar gases. Investigators also have used the O_2 and CO_2 concentration gradients in soil in an attempt to estimate the rate that VOCs or hydrocarbons are being biodegraded. Thus, because of these properties, it is generally considered that Fick's law would not be a valid approach to modeling the movement of these gases, and the Stefan–Maxwell equations (Amali and Rolston, 1993; Amali et al., 1996; Evans et al., 2004), the DGM (Massmann and Farrier, 1992; Sleep, 1998; Webb and Pruess, 2003; Fen and Abriola, 2004), or "adjusted" Fick's law (Freijer and Leffelaar, 1996; van de Steene and Verplancke, 2006) are deemed more appropriate. This application will usually require knowledge of all three gas transport parameters (D_p, k_a, and D_H). Some studies (Sleep, 1998; Fen and Abriola, 2004) show that the DGM is superior to the others for modeling the movement of VOCs in soils.

8.7.5 Radon Transport into Structures

Radon gas is formed in soil from the radioactive decay of naturally occurring radium within the upper few meters of the vadose zone. Radon is a significant human health concern because of radon entering buildings and the inhalation of the gas that may potentially cause lung cancer. Radon moves through soil primarily by diffusion except in the near proximity to buildings. Near buildings, radon enters buildings primarily through cracks in basement floors and walls by advective gas transport due to pressure differences within and below the building (Nazaroff, 1992). This advective flow is driven by barometric pressure changes, wind, temperature differences, and by operation of heating and air-conditioning systems. It is estimated that diffusion accounts for about 10% of the transport into single family structures and that advection contributes the other 90% (Nazaroff, 1992). Since radon gas occurs in very small concentrations, it may be considered to be a trace gas and Fick's law for describing the diffusion part of the transport process should be applicable. For advection, Darcy's law has been used to describe the gas flow into and around buildings (Riley et al., 1996; Robinson et al., 1997). For a thorough discussion of radon transport through porous media and into buildings, see Nazaroff (1992). Again, this application will usually require knowledge of all three gas transport parameters (D_p, k_a, and D_H).

8.7.6 Volatile Organic Vapor Transport into Structures

A focus area for soil-gas transport in relation to human health stems from the numerous contaminated soil sites around the world, most of which are in urban areas, causing intrusion of volatile organic vapors (e.g., gasoline compounds such as benzene and chlorinated compounds such as trichloroethylene) from soil into buildings. Moisture conditions below buildings greatly impact vapor intrusion due to moisture controls on the soil-gas diffusivity, dispersion coefficient, and air permeability (Tillman and Weaver, 2007). The pathways and controls will be similar to those discussed for radon (previous section). Two technology

barriers preventing realistic assessment of indoor air problems from vapor intrusion are (a) lack of knowledge of actual moisture conditions and its temporal and spatial variability under and around buildings and (b) current risk assessment models for soil contribution to indoor air concentrations (e.g., USEPA, 1996; DKEPA, 2002) where general simulation tools for predicting diffusive and convective gas transport have only considered traditional models such as the Millington and Quirk model for gas diffusivity (Equation 8.26) that do not reflect intact soil conditions across soil types and moisture conditions. However, the new generation of simulation models for the soil vadose zone including the HYDRUS-1D and 2D packages (Simunek et al., 2008) allows for use of more realistic models based on transport parameters in both soil liquid and gaseous phases and will in time facilitate more realistic simulations of vapor transport and intrusion as well as the other key application areas of gas transport theory discussed in this chapter.

Soil Thermal Regime

9.1 Introduction

What is temperature, and more specifically, what is soil temperature? Temperature is a measure of the average kinetic energy of the molecules of a substance. As kinetic energy increases, the temperature increases. At the macroscale, temperature is a physical property that determines the direction of heat flow between two substances in thermal contact. Heat flows from high temperature to low temperature. Temperature is not a measure of heat content. In order to specify the heat content of a particular substance (e.g., soil), both the heat capacity and the temperature must be known.

Why is soil temperature important? Temperature influences many biological, chemical, and physical processes that occur in the soil. Plant germination and growth are closely related to soil temperature. Below a soil temperature of about 5°C, growth of roots of most plants is negligible. When a soil freezes, most biological activities and chemical processes essentially cease. Pesticide degradation, residue decomposition, soil microbiological activity, and nutrient cycles are affected by soil temperature. Soil temperature gradients affect soil moisture and solute movement. Soil temperature affects soil hydraulic conductivity, transport properties, and important environmental processes such as soil–atmosphere gas exchanges, the global carbon cycle, and the transformations and transport of contaminants. Crop growth and evapotranspiration models require accurate submodels of the soil temperature regime. Climate modeling and remote sensing require additional ground-truth data for both soil heat flux and temperature of the surface soil.

Soil temperature is highly dynamic and is influenced by a multitude of factors. Those factors include soil thermal properties, surface mulch, tillage, precipitation, air temperature, incoming radiation, fire, vegetation, snow cover, soil color and organic-matter content, aspect and slope, elevation, and groundwater. All these factors have some influence on soil temperature, and they contribute to the great diversity of soil temperature regimes.

Soil temperature may range from highs of near 700°C at the surface during an intense forest fire (Neary et al., 1999) to lows of –20°C during the Arctic winter (Coulson et al., 1995). At the local scale, soil temperature varies horizontally, vertically, and temporally. Local horizontal variations in soil temperature arise from differences in plant cover and surface shading (Figure 9.1), variability in soil moisture and density, or distance from buried heat sources. Horizontal gradients in soil surface temperature under a partially developed row crop canopy (or partial mulch cover) can exceed 1°C cm^{-1} (Horton et al., 1984a).

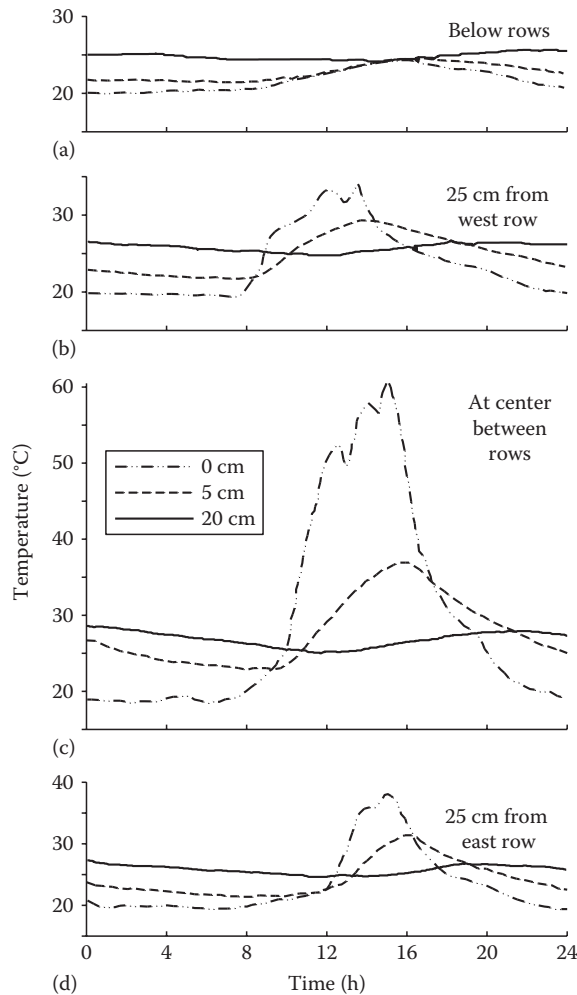
Vertical soil temperature variations are primarily driven by the fluctuating temperature of the soil surface. Heat is both absorbed at and lost from the surface of the soil. The soil transmits heat


FIGURE 9.1 Soil temperature with time at 0, 5, and 20 cm below the soil surface as measured between two NE–SW-oriented rows of 60 cm tall chili (*Capsicum annuum* L.) plants. The rows were 100 cm apart, (a), (b), (c), and (d) show diurnal soil temperatures measured at locations beneath rows, 25 cm from the west row, at the center between rows, and 25 cm from the east row, respectively. (Reprinted from Horton, R., O. Aguirre-Luna, and P.J. Wierenga. 1984a. Observed and predicted two-dimensional soil temperature distributions under a row crop. Soil Sci. Soc. Am. J. 48:1147–1152.)

downward when the temperature near the surface is higher than the temperature below, and it transmits heat upward when the temperature is warmer within the soil than at the surface. During warming periods, the soil temperature is greatest near the surface and lower at depth. During cooling periods, the reverse is true. Thus, for most environments, both the highest and lowest observed soil temperatures occur at the surface. Under conditions of dry soil and high incoming radiation, vertical soil thermal gradients near the surface can exceed 10°C cm^{-1} (Heitman et al., 2008c).

Soil temperature also changes with time. In many, but not all, cases, soil temperatures exhibit distinct daily and annual cycles. The cycles deeper in the soil lag behind those near the surface. The daily cycles decrease in amplitude as depth increases, and below 35 cm, amplitudes become quite small in most soils (Figure 9.2). Annual cycles are observable to greater depths than

daily cycles, if seasonal air temperature differences occur. Thus, annual soil temperature cycles are much less pronounced near the equator than in the middle and high latitudes. Seasonal temperature differences decrease, and the annual cycles lag progressively as depth increases. The amplitude of the annual temperature cycle at depths >8 m is 5% or less of the amplitude at the soil surface, and the temperature at these depths approximates the mean annual temperature of the shallower soil (Baker and Baker, 2002; Smerdon et al., 2003).

For soils that freeze in winter, soil temperature is influenced by the release of heat when liquid water becomes ice. The amount of heat released is about 334 J g^{-1} of water that freezes. The heat of fusion energy must be dissipated while soil water freezes. The rate of thaw of frozen soils is relatively slow, because heat energy is required to both warm the soil and melt the ice. In areas of heavy snowfall, the snow provides an insulating blanket and soils do not freeze as deeply or may not freeze at all.

The soil thermal regime is one of the defining characteristics of a soil. The USDA soil classification system (Soil Survey Staff, 1999) includes soil temperature regimes based on temperature at a depth of 50 cm or at the upper boundary of a root-limiting layer, whichever is shallower. The soil temperature regimes, defined in terms of the mean annual soil temperature and the difference between mean summer and mean winter temperatures, are determined by the following groupings:

Gelisols and gelic suborders and great groups are assigned to soil temperature regimes based on their mean annual soil temperature as follows: *hypergelic* (–10°C or lower), *pergelic* (–4°C to –10°C), and *subgelic* (1°C to –4°C).

Other soils that have a difference in soil temperature of 6°C or more between mean summer and mean winter temperatures are assigned to soil temperature regimes based on their mean annual soil temperature as follows: *frigid* (lower than 8°C), *mesic* (8°C–15°C), *thermic* (15°C–22°C), and *hyperthermic* (22°C or higher).

All other soils are assigned to soil temperature regimes based on their mean annual soil temperature as follows: *isofrigid* (lower than 8°C), *isomesic* (8°C–15°C), *isothermic* (15°C–22°C), and *isohyperthermic* (22°C or higher).

9.2 Mechanisms of Heat Transfer in Soil

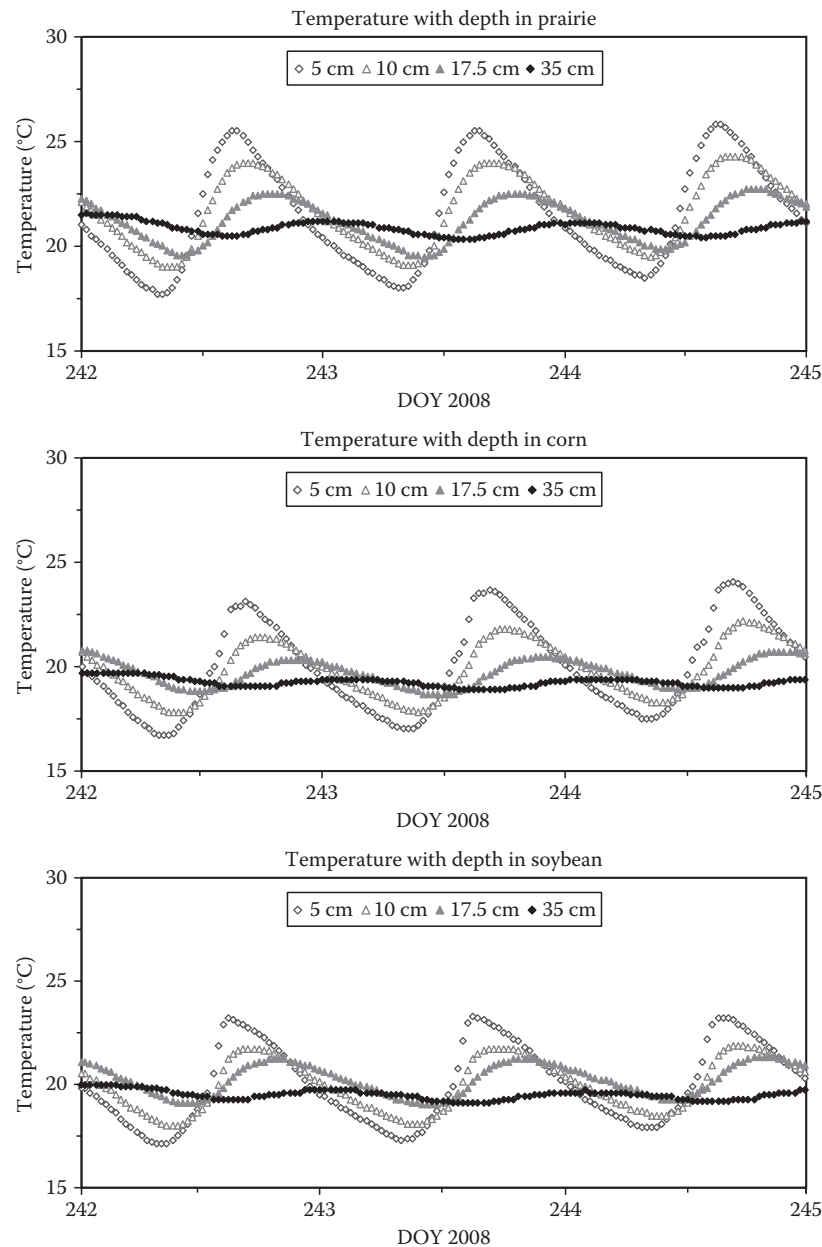
Three principal mechanisms, radiation, convection, and conduction, are responsible for the transfer of heat in soil simultaneously. Radiative energy transfer includes incoming direct and diffuse solar (shortwave) radiation, as well as longwave sky radiation to the soil surface and longwave radiation emitted outward from the soil surface. Radiative transfer is a significant component of heat transfer at the soil surface, but its significance decreases below the soil surface. Convective heat transfer in soil is associated with a net flux of fluids. Convection may be responsible for a major portion of the soil heat transfer during periods of large water flux (e.g., during rainfall or irrigation). Convection is also important via vapor fluxes in shallow unsaturated soil layers when large thermal gradients occur. Although radiation and convection are each important mechanisms of soil heat transfer


FIGURE 9.2   Soil temperature variation with depth and time for several Iowa fields.

under certain conditions, conduction is typically the dominant mechanism of heat transfer within the soil. Conduction heat transfer involves the transfer of heat at a molecular scale from positions of large kinetic energy (high temperature) to positions of small kinetic energy (low temperature).

We will consider that radiation heat transfer is restricted to the surface. That leaves convection and conduction as heat transfer mechanisms to be considered within soil. Most authors focus on conduction heat transfer as the primary mechanism of heat transfer in soil. They assume that conduction predominates at times other than rainfall or irrigation. Buchan (2001) is somewhat unique in his presentation of soil heat transfer processes in that he includes conduction and convection heat transfer

simultaneously. This is good because in soil, conduction and convection often occur together.

Transfer of heat and water in soil is generally coupled, which is to say that the transfer processes are intertwined. Water moving into and through the soil carries heat with it, and temperature gradients in the soil cause movement of both liquid water and water vapor. In a typical diurnal cycle, the soil surface loses heat during the night. The surface temperature drops, and the resulting upward thermal gradient results in transfer of heat to the surface from the relatively warm soil below. If the surface temperature drops to the dew point temperature, water vapor condenses at the cooled soil surface, liberating more heat. Throughout the night, liquid water flows upward, rewetting

surface layers that had dried during the previous day and redistributing heat upward. In the morning, solar radiation warms the soil surface. As the surface temperature increases, the thermal gradient shifts direction. Liquid water near the soil surface vaporizes and is transported into the atmosphere, taking large quantities of heat with it. Liquid water and water vapor are also driven by the thermal gradient from the hot surface to the cooler soil below. As the sun goes down, the dynamic and intricate cycle begins again.

9.3 Surface Energy Balance

The complexities and significance of the soil thermal regime find full expression in the deceptively simple and widely used equation for the energy balance of the land surface:

$$R_n + H + LE + G = 0, \qquad (9.1)$$

where

R_n is net radiation at the surface
H is sensible heat flux between the surface and the atmosphere
LE is latent heat flux between the surface and the atmosphere
G is the total heat flux (sensible and latent) between the surface and the subsurface

Here, all the fluxes are positive toward the surface and expressed in units of watt per square meter.

Comprehensive surface energy balance studies have been conducted since the 1950s. Works by Lettau and Davidson (1957) and Lemon (1963) are early examples of these types of studies. In recent years, with technical advancement of ground-based and remote sensing instrumentation, surface energy balance measurements have become much more common. This trend is evidenced by the development of the global energy balance archive (GEBA) for documentation of current climatic conditions and facilitation of the study of past and future climate (Gilgen and Ohmura, 1999). The spatial scale of energy balance studies has also expanded with advancing sensor technology. For example, interest in global climate change has prompted several efforts to estimate the earth's annual mean energy budget (e.g., Ohmura and Gilgen, 1993; Kiehl and Trenberth, 1997).

Some authors have defined H, LE, and G as positive away from the surface, in which case the "plus" signs are replaced with "minus" signs in Equation 9.1. With that convention, Equation 9.1 is often rearranged to set R_n equal to the sum of the other three terms. Such presentation promotes the idea that net radiation is partitioned into heating the air, heating the soil, and evaporating water. This thinking is only partially true. By isolating the net radiation term, proper importance is assigned to the radiative energy that derives from the sun. However, the net radiation includes more than solar energy. The implication that R_n is the driver and that the other processes are the followers is not completely true. A more accurate representation is given in Equation 9.1. The four components of the energy balance are interdependent. The surface temperature affects all four terms, including R_n. The surface temperature, in turn, is a result of the energy partitioning that includes all four terms of Equation 9.1. In the following sections, the four terms of Equation 9.1 are briefly considered for the case of a bare soil surface. We refer readers to Chapter 6 for a more comprehensive presentation of surface energy balance.

9.3.1 Net Radiation

Net radiation (R_n) is defined as incoming minus outgoing radiation at the land surface. Net radiation can be described by the following:

$$R_n = (1 - a)R_g + R_l - \varepsilon\sigma T_s^4, \qquad (9.2)$$

where

a is surface albedo
R_g is global (i.e., direct plus diffuse solar) radiation (W m^{-2})
R_l is downward longwave sky irradiance (W m^{-2})
ε is surface emissivity
σ is the Stefan–Boltzmann constant (5.67 × 10^{-8} W m^{-2} K^{-4})
T_s is surface temperature (K)

The soil surface temperature can be measured with thermocouples or by infrared thermometers (Ham and Senock, 1992).

9.3.2 Sensible and Latent Atmospheric Heat Fluxes

Horton and Chung (1991) used the following equations to calculate surface latent and sensible heat fluxes:

$$LE = \frac{L(\rho_{va} - \rho_{vs})}{r_{va}}, \qquad (9.3)$$

$$L = 2.49463 \times 10^9 - 2.247 \times 10^6 \, (T_s - 273.15), \qquad (9.4)$$

$$H = \frac{C_a(T_a - T_s)}{r_A}, \qquad (9.5)$$

where

E is the evaporative flux (m s^{-1})
L is the latent heat of vaporization (J kg^{-1})
ρ_{va} is vapor density of the air (kg m^{-3})
ρ_{vs} is vapor density of the surface (kg m^{-3})
r_{va} and r_A are the aerodynamic boundary layer resistances (s m^{-1}) to vapor and heat transfer
C_a is air volumetric heat capacity (J m^{-3} °C^{-1})
T_a is air temperature

Some studies suggest that an additional soil surface resistance parameter be added to the numerator in Equation 9.3 to more accurately represent evaporation when the soil surface is dry (Saito et al., 2006).

The vapor density at the surface, ρ_{vs}, can be calculated from the Kelvin equation as

$$\rho_{vs} = \rho_{vs}^{\star} \exp\left[\frac{(M_w \psi)}{(RT_s)}\right], \qquad (9.6)$$

where

$\rho_{vs}^{\star}$ is the saturated vapor density (kg m^{-3})

M_w is the molecular weight of water (kg mol^{-1})

ψ is the water potential (sum of osmotic and matric) at the surface (J kg^{-1})

R is the universal gas constant (8.314 J mol^{-1} K^{-1})

Note that Equations 9.2, 9.4 through 9.6 show that R_n, LE, and H are each influenced by surface temperature. Therefore, the terms cannot be considered to be independent of each other. Several approaches for solving the surface energy balance equations for T_s have been developed (e.g., Bristow, 1987; Horton and Chung, 1991).

9.3.3 Sensible and Latent Soil Heat Flux

The final term in Equation 9.1 is G, the soil heat flux. The amount of sensible and latent energy that moves through an area of soil in a unit of time is the soil heat flux or heat flux density, G. The ability of a soil to conduct heat impacts how fast its temperature changes during a day or between seasons. Soil heat flux is important because it effectively couples energy transfer processes at the surface (surface energy balance) with energy transfer processes in the soil (soil thermal regime). This interaction between surface and subsurface energy transfer processes has led to detailed investigations of soil heat flux for a wide variety of agricultural systems (Sauer, 2002; Sauer and Horton, 2005).

The magnitude of G as a component of the surface energy balance varies with surface cover, soil moisture content, and solar irradiance (Sauer and Horton, 2005). Daytime peak hourly values of G for a bare, dry soil in midsummer, could be in excess of 300 W m^{-2} (Fuchs and Hadas, 1972). By contrast, hourly G for a moist soil beneath a plant canopy, residue layer, or snow cover will often be less than ±20 W m^{-2}. Surface soil heat flux typically represents 1%–10% of daily R_n for growing crops with full canopy coverage (Denmead, 1969; Szeicz et al., 1973; Brown, 1976; Uchijima, 1976; Baldocchi et al., 1985; Clothier et al., 1986). This percentage can exceed 50% in the fall and spring when R_n is low and the soil is cooling/warming or in arid climates when there is no vegetation (Monteith, 1958; Idso et al., 1975; Choudhury et al., 1987).

Figure 9.3 provides example curves of the energy balance terms for a corn (*Zea mays* L.) residue-covered soil in central Iowa (Sauer et al., 1998). The data in Figure 9.3 were obtained in November when the soil and fresh residue layers were dry and the mean surface temperature was 6.8°C. Daytime G averaged 14.4% and 16.8% of R_n for days 310 and 311, respectively. Much of the energy that enters the soil during the day returns to the atmosphere at night through terrestrial longwave radiation. For this reason, G is often the smallest component of the daily
FIGURE 9.3 Energy balance components measured above a corn residue-covered soil surface in 1994 at a site near Ames, Iowa. Net radiation (R_n) is positive toward the surface. The other terms are positive away from the soil surface. (Reprinted from Sauer, T.J., J.L. Hatfield, J.H. Prueger, and J.M. Norman. 1998. Surface energy balance of a corn residue-covered field. Agric. For. Meteorol. 89:155–168, Copyright (1998), with permission from Elsevier.)

surface energy balance and has, in some cases, been ignored. However, there are often significant transfers of energy into and out of a soil during both day- and nighttime hours, and failure to include G in short-term (i.e., hourly) energy balance determinations can lead to significant errors. Later in this chapter, we consider methods to estimate and measure G.

9.4 Soil Thermal Properties

The three main soil thermal properties are volumetric heat capacity (C), thermal conductivity (λ), and thermal diffusivity (α). Because $\alpha \equiv \lambda C^{-1}$, knowledge of any two of the three properties is sufficient information to calculate the third property. Soil thermal properties are generally expressed as a function of soil water content. For example, Ren et al. (1999) reported soil thermal property values for two soils as a function of water content (Figure 9.4). Ochsner et al. (2001) studied soil thermal properties as a function of soil solid, liquid, and gas fractions. For a range of soils, they found that soil air content exerted the most dominant influence on soil thermal properties (Figure 9.5). The effective or apparent thermal properties of soil at temperatures below freezing can also be strongly temperature dependent due to latent heat effects associated with the liquid–solid phase change of soil water (Figure 9.6; Ochsner and Baker, 2008).

9.4.1 Soil Thermal Conductivity

Heat flow in soil has often been considered analogous to heat flow in a solid to which Fourier's law is applied:

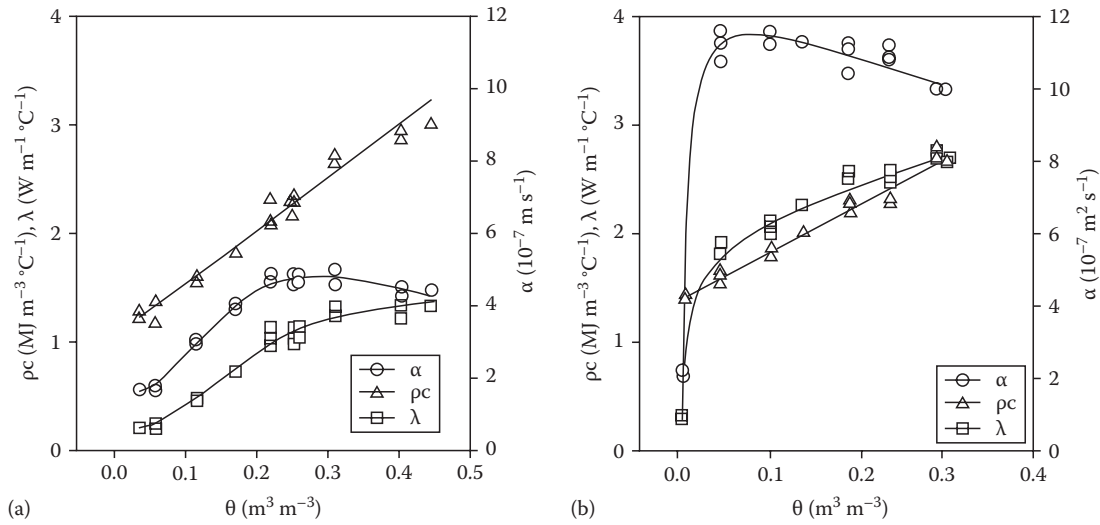
$$G = -\lambda \frac{dT}{dz} \qquad (9.7)$$


FIGURE 9.4 Thermal properties of clay loam soil (a) and silica sand (b) as functions of volumetric water content. (Reprinted from Ren, T., K. Noborio, and R. Horton. 1999. Measuring soil water content, electrical conductivity, and thermal properties with a thermo-TDR probe. Soil Sci. Soc. Am. J. 63:450–457. With permission. Soil Science Society of America.)

FIGURE 9.6 Apparent thermal properties of silt loam soil for temperatures just above and below 0°C. Thermal properties were measured in situ (symbols) using an HP method. Thermal properties were modeled (lines) using the approach of Fuchs et al. (1978). (Reprinted from Ochsner, T.E., and J.M. Baker. 2008. In situ monitoring of soil thermal properties and heat flux during freezing and thawing. Soil Sci. Soc. Am. J. 72:1025–1032. With permission. Soil Science Society of America.)

where

 G is the heat flux density (W m^{-2})
 λ is thermal conductivity (W m^{-1} K^{-1})
 d*T*/d*z* is the temperature gradient (K m^{-1})

Thermal conductivity is a measure of the soil's ability to transmit heat. It is the ratio of the magnitude of the heat flux through the soil to the magnitude of the temperature gradient. Fourier's law is easily and directly utilized in many engineering applications; however, in a porous, three-phase media like soil, specifying λ is considerably more difficult.

 Unsaturated soils consist of three phases: solid, liquid, and gas. The different materials within soils have different thermal conductivities. Both fractional makeup and physical arrangement of

TABLE 9.1 Density, Specific Heat and Thermal Conductivity of Common Soil Constituents at 10°C

Soil Constituent	Density (ρ) (Mg m^{-3})	Specific Heat (*c*) (kJ kg^{-1} K^{-1})	Thermal Conductivity (λ) (W m^{-1} K^{-1})
Quartz	2.66	0.75	8.8
Clay minerals	2.65	0.76	3
Soil organic matter	1.3	1.9	0.3
Water	1.00	4.18	0.57
Ice (0°C)	0.92	2.0	2.2
Air	0.00125	1.0	0.025

 Source: After de Vries, D.A. 1963. Thermal properties of soils, p. 210–235. *In* W.R. van Wijk (ed.) Physics of plant environment. North-Holland Publishing Co., Amsterdam, the Netherlands, Table 7.1.

materials affect the overall thermal conductivity of soils. Two of the major factors affecting thermal conductivity of porous materials are water content (θ) and bulk density (ρ_b). In general, λ of solid > λ of liquid > λ of gas. Therefore, increasing the bulk density or water content of a soil should lead to increases in λ. Al Nakshabandi and Kohnke (1965), for instance, measured an eightfold increase in the thermal conductivity of a silt loam soil as its water content increased. The thermal conductivity of soil also varies by composition of the solid fraction (e.g., mineral type, particle size, and amount of organic matter) (Al Nakshabandi and Kohnke, 1965; Abu-Hamdeh and Reeder, 2000). In particular, the thermal conductivity increases with quartz content because quartz has a higher thermal conductivity than other common soil minerals (Bristow, 1998). de Vries (1963) presented average values of thermal conductivity for various soil constituents and those values are reproduced here in Table 9.1.

 Temperature is another parameter that influences thermal conductivity. de Vries (1963) found that thermal conductivity of a sandy soil increased with increasing water content and with temperature until 60°C. At a temperature of 75°C, the thermal conductivity increased with increasing water content until 0.1 m^3 m^{-3}, but then decreased as water content increased. In unsaturated soil, conduction is not the only heat transfer mechanism influencing λ. Evaporation, movement, and condensation of water vapor in the soil pores also influence λ. These latent heat transfer processes become more important as soil temperature increases, but they can be inhibited when liquid water content fills the majority of the pore space.

 The properties that influence λ vary between soils, spatially at the soil surface for the same soil, between layers within a soil, and over time. Because of this variability, much effort has been made to develop λ models based on easily measurable soil parameters (Kersten, 1949; de Vries, 1963; Johansen, 1975; Campbell; 1985; Côté and Konrad, 2005). The available models can be divided into two groups: semi-theoretical models and empirical models.

 The de Vries (1963) model is a physically based, semi-theoretical model, which has been applied in numerous studies, including predicting the response of λ to temperature change (Hopmans

and Dane, 1986; Campbell et al., 1994). In the de Vries model, the thermal conductivity of soil is calculated as the weighted average of the conductivities of the various soil constituents according to the formula:

$$\lambda = \frac{\sum_{i=0}^{n} k_i \lambda_i x_i}{\sum_{i=0}^{n} k_i x_i},$$ (9.8)

where

x_i is the volume fraction of each constituent
λ_i is the thermal conductivity of each constituent
n is the number of soil constituents

The weighting factors, k_i, depend on the shape and orientation of the granules of the soil constituents and on the ratio of the conductivities of the constituents. The subscript 0 refers to the continuous fluid surrounding the solid particles (i.e., air for dry soil and water for moist soil) with $k_0 = 1$. Other values of k_i are calculated from

$$k_i = \frac{1}{3} \sum_{j=1}^{3} \left[1 + \left(\frac{\lambda_i}{\lambda_0} - 1 \right) g_j \right]^{-1},$$ (9.9)

where g_j represents the shape factors for the ith constituent, and $g_1 + g_2 + g_3 = 1$. Assuming g_1 and g_2 are equal, only one shape factor needs to be estimated for each constituent.

The thermal conductivity of the air-filled pores is considered to be the sum of λ_a and λ_v, where λ_a is the thermal conductivity of dry air (0.025 W m^{-1} K^{-1} at 20°C), and λ_v accounts for heat transfer across the air-filled pores by water vapor. Above some critical water content, the air-filled pores are assumed to be saturated with water vapor, and λ_v is assumed to be 0.074 W m^{-1} K^{-1} at 20°C. Below the critical water content, λ_v is assumed to decrease linearly with water content to a value of zero for oven-dry soil. Assuming a soil solid particle shape factor of 0.144, then for water contents above the critical water content, the value of g_1 for the air-filled pores is given by

$$g_1 = 0.333 - \frac{n_a}{(1 - v_s)}(0.333 - 0.035),$$ (9.10)

where n_a and v_s are the volume fractions of air and solids, respectively.

For water contents below the critical water content, the value of g_1 for the air-filled pores is given by

$$g_1 = 0.013 + \frac{\theta}{\theta_c}(g_{1c} - 0.013),$$ (9.11)

where

θ_c is the critical water content
g_{1c} is the value of Equation 9.10 at the critical water content

The de Vries model has proven useful for many years, but proper (and somewhat subjective) selection of model parameters, such as critical water content and shape factors, is necessary to predict λ accurately (Horton and Wierenga, 1984; Ochsner et al., 2001).

There is a great diversity of empirical models for λ. One of the earliest is that of Kersten (1949). This model only requires bulk density as an input parameter, but the model is not suitable for predicting λ at lower water contents (Côté and Konrad, 2005). Campbell (1985) introduced an empirical function to calculate λ. The empirical function has five parameters, some of which are difficult to estimate. Johansen (1975) proposed the concept of normalized thermal conductivity and established a simple empirical model based on the degree of saturation and soil mineral composition. For many soils, the Johansen (1975) model provides accurate predictions of λ (Farouki, 1981, 1982; Tarnawski and Wagner, 1992). Nevertheless, the Johansen (1975) model does not cover the entire water content range. Lu et al. (2007) presented an improved model describing the relationship between thermal conductivity and volumetric water content. The new model was calibrated using measured thermal conductivity from eight soils, and it was validated by comparing predicted λ with measured λ on 19 additional soils. The model performed well for a wide range of soils and was applicable over the entire range of soil water contents. Frozen soil represents a special condition. Farouki (1986) provides insight on observations and predictions of thermal properties for frozen soil conditions.

9.4.2 Soil Heat Capacity

Soil heat capacity characterizes the quantity of heat added to or removed from soil per unit change in temperature. Heat capacity has an important role in determining the magnitude of diurnal and annual soil temperature variations. In soil with low heat capacity, the addition or removal of heat causes a relatively large soil temperature change, and in soil with large heat capacity, the addition or removal of heat causes a relatively small temperature change.

The volumetric heat capacity of soil is calculated as the weighted sum of the heat capacities of the various soil constituents (Kluitenberg, 2002). Thus,

$$C = \sum_{i=1}^{n} x_i C_i = \sum_{i=1}^{n} x_i \rho_i c_i,$$ (9.12)

where x_i and C_i (J m^{-3} K^{-1}) represent the volume fractions and volumetric heat capacities, respectively, of n soil constituents. This relationship shows that the volumetric heat capacity of each constituent is the product of its density ρ_i (Mg m^{-3}) and its specific heat c_i (J kg^{-1} K^{-1}). Equation 9.12 can be expressed in terms of mass fractions ϕ_i by using the relationship:

$$x_i = \frac{\phi_i \rho_b}{\rho_i},$$ (9.13)

where ρ_b is the soil bulk density. Substituting Equation 9.12 into Equation 9.13 yields

$$C = \rho_b \sum_{i=1}^{n} \phi_i c_i. \tag{9.14}$$

In order to use Equation 9.14, knowledge is needed of the specific heats of the various constituents present in soil. Approximate specific heat values for soil constituents are provided in Table 9.1. Because soil air makes a negligible contribution to C, it is common to write Equation 9.14 as

$$C = \rho_b(c_m \phi_m + c_o \phi_o + c_w \theta_g), \tag{9.15}$$

where
the subscripts m, o, and w indicate mineral material, organic material, and water, respectively
θ_g is the gravimetric water content

The mineral and organic fractions of soil can be lumped to give an average specific heat of the solid constituents, c_s,

$$C = \rho_b(c_s + c_w \theta_g). \tag{9.16}$$

9.4.3 Soil Thermal Diffusivity

Soil thermal diffusivity, α, is defined as the ratio of thermal conductivity to volumetric heat capacity. Thermal diffusivity often appears in partial differential equations describing soil heat transfer and in the solutions to those equations. Soil thermal diffusivity is the parameter that describes the rate of transmission of a temperature change through the soil. The higher the thermal diffusivity, the more rapid the propagation of temperature changes through the soil. Thermal diffusivity can be estimated by using appropriate models to calculate thermal conductivity and heat capacity and then taking the ratio. Procedures for measuring thermal properties, including diffusivity, are discussed below.

9.4.4 Measuring Soil Thermal Properties

Considerable effort has gone into developing methods for measuring soil thermal properties. The line-source thermal sensor (with single needle or multiple needles) has been the primary method. When using a single-needle sensor, temperature with time data are obtained during and just after the needle is heated. The thermal conductivity can be calculated from the temperature data (Jackson and Taylor, 1965; Horton and Wierenga, 1984; Shiozawa and Campbell, 1990).

de Vries and Peck (1958) reported that it may be possible to determine λ and α simultaneously with a single-needle sensor. The unknown contact resistance between the line-source sensor

and soil is a practical inhibitor to accurate results. Bruijn et al. (1983) and van Haneghem et al. (1983) presented and tested the theory for simultaneously determining λ and C by accounting for contact resistance between sensor and soil. Other investigators have recognized that measurement of temperature (multineedle sensors) at a known distance away from a heat source provides opportunity for simultaneous determination of thermal properties (Lubimova et al., 1961; Chudnovski, 1962; Jaeger, 1965; Nix et al., 1967, 1969; Larson, 1988; Kluitenberg et al., 1993, 1995; Bristow et al., 1994; Bilskie et al., 1998).

Bristow et al. (1994) showed that using short-duration heat-pulse (HP) theory, λ, C, and α could be determined from a single HP measurement using a dual-probe sensor as described by Campbell et al. (1991). This method is commonly referred to as the dual-probe HP method or simply the HP method. Figure 9.7 shows diagrams of a typical dual-probe HP sensor. The HP method is based on the theory of radial heat conduction of a short-duration heat pulse from an infinite line source. In an infinite medium, the temperature change as a function of time at a radial distance from the HP source is given by (de Vries, 1952; Kluitenberg et al., 1993):

$$\Delta T(r, t) = \frac{Q}{4\pi\alpha}\left[Ei\left(\frac{-r^2}{4\alpha(t - t_0)}\right) - Ei\left(\frac{-r^2}{4\alpha t}\right)\right], \quad t > t_0 \tag{9.17}$$

where
ΔT is the temperature change (°C)
t is time (s)
t_0 is the HP duration (s)
r is the radial distance (m)
$-Ei(-x)$ is the exponential integral

The source strength is defined as $Q = q'/C$, where q' is the rate of heat liberation per unit length of probe (W m^{-1}). Figure 9.8 shows a typical temperature rise curve obtained from an HP measurement.

Based upon Equation 9.17, soil thermal properties can be expressed analytically as (Kluitenberg et al., 1993; Bristow et al., 1994):

$$\alpha = \frac{(r^2/4)[(1/(t_m - t_0)) - (1/t_m)]}{\ln[t_m/(t_m - t_0)]}, \tag{9.18}$$

$$C = \frac{q'}{4\pi\alpha\Delta T_m}\left[Ei\left(\frac{-r^2}{4\alpha(t_m - t_0)}\right) - Ei\left(\frac{-r^2}{4\alpha t_m}\right)\right], \tag{9.19}$$

$$\lambda = \alpha C, \tag{9.20}$$

where
t_m is the time (s) at which the temperature maximum occurred
ΔT_m is the maximum temperature change (°C)
FIGURE 9.7 Diagram of a dual-probe HP sensor. (Reprinted from Kluitenberg, G.J. 2002. Heat capacity and specific heat, p. 1201–1208. *In* J.H. Dane and G.C. Topp (eds.) Methods of soil analysis. Part 4. Physical methods. SSSA, Madison, WI. With permission. Soil Science Society of America.)
FIGURE 9.8 Typical temperature versus time curve for a dual-probe HP measurement. The maximum temperature rise (ΔT_m) and time of the maximum temperature rise (t_m) are indicated.

A more recent simplification of Equation 9.19 was developed by Knight and Kluitenberg (2004):

$$C = \frac{q' t_0}{e \pi r^2 \Delta T_m} \left(1 - \frac{\varepsilon^2}{8} \left\{ \frac{1}{3} + \varepsilon \left[\frac{1}{3} + \frac{\varepsilon}{8} \left(\frac{5}{2} + \frac{7\varepsilon}{3} \right) \right] \right\} \right), \quad (9.21)$$

where

$\varepsilon = t_0 / t_m$

e is the base of the natural logarithm

Equation 9.21 employs a telescoped polynomial rather than the exponential integral and is thus easier to use in spreadsheets and on-board dataloggers. Further details regarding the application of the HP method are given by Kluitenberg (2002) and Bristow (2002). One important application of the HP method is in monitoring soil water content (Tarara and Ham, 1997; Campbell et al., 2002;

Heitman et al., 2003; Ochsner et al., 2003). Soil water content can be estimated with the HP method by utilizing the linear dependence of C on the soil water content (Equation 9.16).

9.5 Modeling the Soil Thermal Regime

Heat transfer modeling offers the following contributions: (1) it describes energy partitioning at the soil surface; (2) it describes soil heat flux within the soil profile; and (3) it describes soil temperature distribution. The surface-energy partitioning and resulting soil temperature distribution directly and indirectly affect plant growth and development, and many biological, chemical, and physical processes in the soil.

9.5.1 Conduction Models

Analytical and numerical solutions to the following 1D, transient conduction equation for various initial and boundary conditions have been presented in the literature:

$$C \frac{\partial T}{\partial t} = \frac{\partial}{\partial z} \left(\lambda \frac{\partial T}{\partial z} \right). \quad (9.22)$$

In many cases, heat transfer by radiation, convection, and conduction is modeled by the conduction equation alone (Wierenga and de Wit, 1970; Hanks et al., 1971; Gupta et al., 1981, 1983; Horton et al., 1984a, 1984b; Parton, 1984; Persaud and Chang, 1984). Apparent thermal properties rather than real thermal properties (Jackson and Kirkham, 1958) are assumed to account for both conductive and nonconductive heat flow. Several investigators have also modeled soil heat transfer in two dimensions (Takakura et al., 1971; Jury and Bellantuoni, 1976a, 1976b; Mahrer and Katan, 1981;

Mahrer, 1982; Horton et al., 1984a, 1984b; Chung and Horton, 1987; Horton, 1989; Benjamin et al., 1990; Kluitenberg and Horton, 1990; Novak, 1993). Two-dimensional models have been used to analyze soil heat transfer beneath row crops, in ridged surfaces, and beneath partial mulch covers. Some of the models include conduction heat transfer alone, and some consider soil water impacts on thermal properties and/or soil water movement (Wierenga and de Wit, 1970; van Bavel and Hillel, 1975, 1976; Sophocleous, 1979; Milly, 1982; Campbell, 1985; Ross et al., 1985; Bristow et al., 1986; Lascano et al., 1987; Pruess and Wang, 1987; Bear and Bensabat, 1989; Nassar and Horton, 1989b, 1989c, 1992; Horton and Chung, 1991; Hares and Novak, 1992a, 1992b; Nassar et al., 1992a, 1992b; Olivella et al., 1994; Scanlan and Milly, 1994; Bear and Gilman, 1995; Gawin et al., 1995; Bristow and Horton, 1996; Noborio et al., 1996a, 1996b; Saito et al., 2006).

For homogeneous, isotropic conditions, the transient conduction equation is as follows:

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial z^2}. \tag{9.23}$$

Analytical solutions to Equation 9.23 exist for certain initial and boundary conditions. Carslaw and Jaeger (1959) have compiled a number of solutions to Equation 9.23 for heat transfer in solids. Although soil does not consist of solids alone, with the assumptions of uniform, constant thermal properties and heat conduction processes dominating, conduction heat transfer theory for solids can be used to approximate heat transfer in soil.

van Wijk and de Vries (1963) present an analytical solution to Equation 9.23 for periodic surface temperature variation for a homogeneous soil. For initial conditions that result from infinite periodic surface temperature variation, semi-infinite space, and surface boundary as

$$T(0, t) = \bar{T} + A\sin(\omega t + \phi), \tag{9.24}$$

where

$\bar{T}$ is the average temperature
A is the amplitude of the surface temperature wave
ϕ is the phase constant
ω is the angular frequency (2π/period, e.g., 2π day^{-1} for diurnal variation)

and the analytical solution is

$$T(z, t) = \bar{T} + A\exp\left(-z\sqrt{\frac{\omega}{2\alpha}}\right)\sin\left(\omega t + \phi - z\sqrt{\frac{\omega}{2\alpha}}\right). \tag{9.25}$$

9.5.1.1 Apparent Thermal Diffusivity

Equation 9.25 provides a basis for estimating the apparent soil thermal diffusivity using measured soil temperature time series. Soil temperature measurements at two or more depths are required. Temperature observations from the shallowest depth are used to establish the upper boundary condition, and the lower depth(s) observations are used to determine α.

Wierenga et al. (1969) presented two methods of determining α based upon Equation 9.25. The first is called the amplitude method. Note that Equation 9.25 indicates that temperature amplitude should decrease exponentially with depth. Wierenga et al. (1969) used the following equation to calculate the apparent thermal diffusivity from the amplitude of the soil temperature wave at two depths:

$$\alpha = \frac{\omega}{2}\left[\frac{z_2 - z_1}{\ln(A_1/A_2)}\right]^2. \tag{9.26}$$

The second approach is the phase method. Note that Equation 9.25 indicates a phase shift as a function of depth. Wierenga et al. (1969) used the following equation to analyze the phase shift of their observations:

$$\alpha = \frac{1}{2\omega}\left[\frac{z_2 - z_1}{\delta t}\right]^2, \tag{9.27}$$

where δt is the time interval between occurrence of maximum soil temperatures at depths z_1 and z_2. Equations 9.26 and 9.27 have been used to give first-order approximations of α. These methods work well for data obtained below a depth of 10 cm (Wierenga et al., 1969). Near the soil surface, Equations 9.26 and 9.27 provide less accurate estimates of α because the soil water content is not uniform and the soil temperature fluctuations are not sinusoidal. Effective use of these equations requires soil temperature measurements at two or more depths at frequent times. The observation period should include two or more sunny days before the days for which soil temperature will be analyzed. The sunny days will allow the soil temperature initial condition to more closely match the theoretical requirements.

As an alternative to Equation 9.24, Horton et al. (1983) used the following general surface boundary condition:

$$T(0, t) = \bar{T} + \sum_{n=1}^{M} A_n \sin(n\omega t + \phi_n), \tag{9.28}$$

and the method of superposition to obtain the following general analytical solution to Equation 9.23:

$$T(z, t) = \bar{T} + \sum_{n=1}^{M} A_n \exp\left(-z\sqrt{\frac{n\omega}{2\alpha}}\right)\sin\left(n\omega t + \phi_n - z\sqrt{\frac{n\omega}{2\alpha}}\right),$$

$$\tag{9.29}$$

where

M is the number of harmonics
A_n and ϕ_n are the amplitude and phase constant, respectively, of the nth harmonic for the upper boundary temperature

The coefficients A_n, ϕ_n, and $\overline{T}$ can be determined by least squares fitting of Equation 9.28 to the observed upper boundary soil temperature data. Using these coefficients in Equation 9.29 leaves only α as an unknown value. The value of α can be determined by fitting Equation 9.29 to a set of soil temperature observations measured at a depth below the upper boundary depth. The value of α is selected to minimize the sum of squares of the differences between the measured and calculated temperatures.

It is important to note that when α is determined from inverse fitting of conductive heat transfer theory to observed temperature, it is not strictly correct to assume that the fitted $\alpha = \lambda/C$. In moist soil, conduction is not the only mechanism of heat transfer. All of the nonconductive heat transfer (sensible and latent convective heat transfer) influences the parameter α. It is more correct to call this α the apparent thermal diffusivity instead of the true or real thermal diffusivity (Jackson and Kirkham, 1958). The real thermal diffusivity involves conduction heat transfer alone, while the apparent thermal diffusivity includes convection heat transfer in addition to conduction heat transfer. The apparent thermal diffusivity is a lumped parameter developed for a practical reason, and while useful for predicting soil temperature, it oversimplifies the many mechanisms of heat transfer within porous media. We should not permit its use to become a hindrance to our basic understanding of the numerous mechanisms of heat and water transfer in soil.

Not all approaches assume that the apparent thermal diffusivity is constant with depth. Nassar and Horton (1989a, 1990) presented methods for determining apparent thermal diffusivity as a function of depth. Again, in these cases, the apparent thermal diffusivity lumps together conductive and convective heat transfer processes. Wiltshire (1982, 1983) and Massman (1993a) presented analytical solutions to describe temperature distributions in nonuniform soil.

9.5.1.2 Soil Heat Flux Models

Transient soil heat flux (G) has also been estimated by analytical solutions to Equation 9.23. The theory assumes that only conduction heat transfer is occurring, so all of the actual convection heat transfer must be accounted for by apparent thermal properties. Conduction heat transfer theory is utilized in a manner to approximate both conduction and convection heat transfer conditions. Horton and Wierenga (1983) presented the following equation for soil heat flux:

$$G(z,t) = \sum_{n=1}^{M} A_n C \sqrt{n\omega\alpha} \, \exp\!\left(-z\sqrt{\frac{n\omega}{2\alpha}} \right)$$
$$\times \, \sin\!\left(n\omega t + \phi_n + \pi/4 - z\sqrt{\frac{n\omega}{2\alpha}} \right). \tag{9.30}$$

Equation 9.30 reduces to the following for surface heat flux:

$$G(0, t) = \sum_{n=1}^{M} A_n C \sqrt{n\omega\alpha} \, \sin\!\left[n\omega t + \phi_n + \left(\frac{\pi}{4}\right) \right] \tag{9.31}$$

Horton and Wierenga (1983) used this analytical solution to estimate heat flux for a bare soil and grass-covered field. The analytical solution worked well for both sunny and cloudy days.

9.5.2 Conduction–Convection Models

A few efforts have been made to measure or describe convective heat transfer under field conditions. Convective energy transfer in soil is associated with a net flux of fluids. Some observations of thermal effects on soil water infiltration have been made (Jaynes, 1990). Increases in seepage or infiltration rate were observed in response to temperature increases (Constantz et al., 2003). Gao et al. (2003) presented an analytical model of transient conduction and steady convection heat transfer. Jaynes (1990) presented a numerical model of heat and water transfer in soil during ponded irrigation. Shao et al. (1998) developed an analytical solution describing coupled conduction and convection heat transfer during ponded infiltration. Shao et al. (1998) reported periodic diurnal fluctuations in ponded infiltration rate. This infiltration rate was correlated with the water temperature. As water temperature oscillated, the infiltration rate oscillated. During infiltration, convection heat transfer had significant effects on soil temperature. Convection is especially important for heat transfer deeper in the soil profile. At a depth of 0.6 m, diurnal temperature variation due to conduction was negligible; however, convection heat transfer caused noticeable diurnal variation in soil temperature. Wierenga et al. (1970) observed irrigation water temperature impacting soil temperature, and Ren et al. (2000), Wang et al. (2002), Hopmans et al. (2002), and Ochsner et al. (2005) have presented conduction–convection models to determine water velocity based upon upstream and downstream temperature measurements in response to an application of a heat pulse.

9.5.3 Coupled Heat and Water Transfer Models

Coupled transfer of heat and water occurs in soil. For example, near the surface of cropland soil, weather fluctuations often cause simultaneous heat and water flow to occur. Buried radioactive material, underground energy storage, and buried electric cables produce heat that causes temperature gradients, which cause water to move. Temperature gradients can cause water to move in the vapor phase from a hot site and to condense at a cold site. After vapor condensation, a total pressure head gradient can drive water from the cold site to the warm site. Example profiles showing the redistribution of soil moisture under imposed temperature gradients are plotted in Figure 9.9.

Coupling of soil heat and water transfer has long been recognized (e.g., Bouyoucos, 1915). Thus, many studies have attempted to address coupled soil heat and water transfer and provide theoretical description of the dominant transfer mechanisms (e.g., Philip and de Vries, 1957; Jury and Letey, 1979; Sophocleous, 1979; Milly and Eagleson, 1980; Milly, 1982; Nassar and Horton, 1997). Several studies have been performed to investigate interactions between heat and water (Philip and de Vries, 1957; Cary, 1966; Globus, 1983). Milly and Eagleson (1980) and Milly (1982) described simultaneous heat and water
FIGURE 9.9 Comparison of paired temperature (T) and water content (θ) distributions for silt loam. Plots (a) and (b) show conditions after 96 h for 150°C m^{-1} temperature gradient at 30°C mean temperature. The dotted line in (b) represents a linear temperature distribution. (Reprinted from Heitman, J.L., R. Horton, T. Ren, and T.E. Ochsner. 2007. An improved approach for measurement of coupled heat and water transfer in soil cells. Soil Sci. Soc. Am. J. 71:872–880. With permission. Soil Science Society of America.)

transfer in terms of matric pressure head and temperature gradients. Their formulation accounted for inhomogeneous soil and hysteresis of the moisture retention process.

Nassar and Horton (1989c) introduced a theory describing water redistribution for conditions involving temperature, water, and solute concentration gradients. This theory was expanded by Nassar and Horton (1992) to include heat, water, and solute movement under soil water content, temperature, and solute concentration gradients. The theory includes several heat and mass transfer coefficients. The water, heat, and solute transport coefficients are usually affected by the water content, temperature, and solute concentration.

There are currently only a limited number of published reports that include values of these coefficients, especially under the combined effect of water content, temperature, and solute concentration (e.g., Nassar and Horton, 1997). Effects of a wide range of soil temperatures, 5°C–55°C, on water redistribution in solute-free soil columns were reported by Nassar et al. (1992a). A net water transfer was found toward the cold ends of the soil columns with increasing mean soil temperature. It was concluded that the temperature dependence of several soil water transfer coefficients affected the water transfer rates.

Values for hydraulic conductivity and isothermal and thermal vapor diffusivities as functions of soil water content and temperature were reported by Scanlon and Milly (1994). Hydraulic conductivity increased with increasing soil water content and temperature. Also, the isothermal and thermal vapor diffusivities increased with increasing temperature whereas they increased with increasing soil water content to certain values then decreased with further increases in the soil water content. Nassar and Horton (1997) describe how to determine experimentally and/or theoretically derived values of the transport coefficients of heat, water, and solute in soils. They present coefficient values as functions of temperature, water content, and solute concentration.

There are limitations in the models used to predict coupled heat and water transfer in soil (e.g., Philip and de Vries, 1957; Cary and Taylor, 1962; Milly, 1982; Nassar and Horton, 1997; Cahill and Parlange, 1998). Cahill and Parlange (1998) and Parlange et al. (1998) report that existing diffusion-based theory could not explain the large vapor fluxes and evaporation rates measured in their field study. They proposed that diurnal heating of the soil causes convective transport of soil air due to temperature-driven expansion of the air, and this convective enhancement (soil breathing) drives the large unexplained water vapor fluxes observed in field studies. This concept has not yet been confirmed. Philip and de Vries (1957) introduced a thermal vapor enhancement factor to account for pore-scale features (e.g., unequal thermal gradients in various phases and nongas phase diffusive pathways in the pores). Using Philip and de Vries theory to describe nonisothermal evaporation, Bachmann et al. (2001) found a thermal vapor enhancement factor of 3.5 (meaning that thermal vapor transport was about 3.5 times larger than expected) in a wettable soil, but only 0.35 in a hydrophobic soil. In other words, soil columns that differed only in wettability showed very different water evaporation rates and water distribution. No existing model can describe the pore-scale behaviors that led to these greatly different thermal vapor enhancement factors. There is growing appreciation for the utility of pore-scale models (e.g., Ewing and Horton, 2007) for gaining insight into the relative importance of coupled transport processes. Hopefully, in the near future, pore-scale models will become further developed, tested, and used to improve understanding and description of coupled heat and water processes in soil.

Diffusion-based theory first introduced by Philip and de Vries (1957) has long been used to describe coupled soil heat and water transfer. Discrepancies between measurements and theory point to the need for more careful evaluation of the theory. Heitman et al. (2008a) used data obtained from laboratory experiments with transient boundary conditions in an attempt to both calibrate and test calculations of coupled heat and water transfer. Simple calibration for a single boundary and initial condition through adjustment of saturated hydraulic conductivity and thermal vapor enhancement factors provided a reasonable match for transient boundary conditions with gradual changes and at additional initial conditions. The findings of Heitman et al. (2008a) indicate that after soil-specific calibration to one coupled heat and water transfer condition,

the Philip and de Vries theory can be used to predict coupled heat and water transfer under other soil conditions.

9.6 Measuring Soil Temperature

Soil temperature is commonly measured using nonelectric thermometers, thermocouples, or thermistors. Nonelectric thermometers operate based on thermal expansion of liquids or solids. These simple devices are appropriate when high accuracy or precision is not required. A thermocouple produces a small voltage (via the Seebeck effect) proportional to the temperature difference between its measuring junction and its reference junction. A sensitive measuring device can be used to measure and record the voltage and corresponding temperature at the measuring junction if the temperature of the reference junction is known by some other means. Thermistors are ceramic semiconductors whose resistance is strongly temperature dependent. By measuring the resistance, one can infer the temperature. Thermistors are generally more sensitive than either nonelectric thermometers or thermocouples. The World Meteorological Organization recommends routine soil temperature measurement depths of 5, 10, 20, 50, and 100 cm (WMO, 2006). A measurement frequency of once every 2 h is often sufficient to describe the diurnal soil temperature cycle. Measurement objectives, available equipment, and site characteristics may dictate different depth and measurement frequency choices. For additional information on soil temperature measurement, consult the chapters by McInnes (2002) and Ochsner (2008).

A significant recent development is the application of distributed temperature sensing in soils. A distributed temperature sensing instrument can be used to determine the temperature at each location along a fiber-optic cable. Temperatures can be measured with a precision of 0.1°C and spatial resolution of 1 m along a cable, which is several kilometers long (Selker et al., 2006). With the aid of a special plow, the cables can be installed at shallow depths below the soil surface and used to measure the spatial distribution of soil temperature over large areas (Steele-Dunne et al., 2010).

9.7 Measuring and Interpreting Soil Heat Fluxes

Researchers have noted the strong connection between soil-water evaporation and soil heat flux (e.g., Gardner and Hanks, 1966; Mayocchi and Bristow, 1995). Unfortunately, an inability to measure heat transfer at the fine scale necessary to observe evaporative processes has limited investigations. Soil heat flux is typically measured below the soil surface, and a correction is made for the change in sensible heat storage above the flux measurement depth (e.g., Fuchs and Tanner, 1968; Massman, 1993b). This approach ignores the transient, depth-dependence of the evaporation front below the soil surface (de Vries and Philip, 1986).

Evaporation plays a central role in the movement of heat and water within the soil (Yamanaka et al., 1998; Wythers et al., 1999) and the atmosphere. For example, evaporation of soil water

accounts for 20% of the heat budget in the Negev during the dry season (Agam et al., 2004). Despite this importance, evaporation is often erroneously described as occurring at the soil surface rather than within the soil. The surface soil heat flux is generally assumed only to account for conductive heat transfer into the soil. This is a restrictive assumption, because as a soil dries from the surface downward, an increasing fraction of the soil-water evaporation occurs below the surface (Mayocchi and Bristow, 1995; Yamanaka et al., 1998). The assumption that all evaporation occurs at the soil surface does not account for the evaporation zone that propagates downward into the soil.

The Community Land Model (CLM3.5; Oleson et al., 2007), perhaps the most detailed of the third-generation land surface models, assumes that evaporation occurs at the soil surface. As a result, soil evaporation estimates are likely to be systematically incorrect (Mahfouf and Noilhan, 1991; Milly, 1992; Guo and Dirmeyer, 2006). The current deficient treatment of the near-surface land/atmosphere coupling is largely due to a lack of appropriate measurement techniques. Aboveground techniques such as eddy covariance (McInnes and Heilman, 2005) and Bowen ratio (Fritschen and Fritschen, 2005) provide useful approaches to estimate evapotranspiration. However, the inability to measure near-surface movement of heat and water has prohibited an accurate assessment of the near-surface water evaporation and heat balance (de Silans et al., 1997). Recent advances in using the HP method for measuring soil thermal properties, heat flux, and heat storage (e.g., Ochsner et al., 2006, 2007) provide a new opportunity to investigate time and depth patterns of heat transfer and evaporation within soil.

9.7.1 Measuring Soil Heat Fluxes

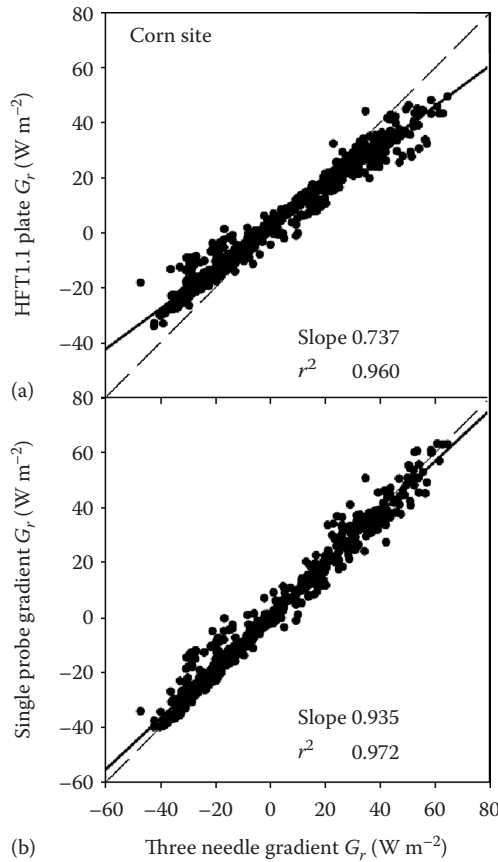
Soil heat flux measurements are most frequently obtained with the use of soil heat flux plates (Sauer, 2002). These small rigid plates contain a thermopile whose voltage output is proportional to the temperature difference between the upper and lower faces of the plate. The relationship between that temperature difference and the conductive heat flux through the plate is calibrated in a laboratory setting. In the field, the assumption is made that the heat flux through the plate is the same as that through the surrounding soil at the same depth; thus, the voltage output from the plate (mV) is divided by an empirical constant (mV m^2 W^{-1}) to estimate the soil heat flux (W m^{-2}). Several criteria must be met for heat flux plates to produce accurate data: (1) there must be negligible thermal contact resistance between the plate and the soil, (2) the thermal properties of the plate must be the same as those of the surrounding soil, and (3) heat transfer through the soil must be by conduction alone. These criteria are rarely, if ever, satisfied in the field; thus, significant errors may be unavoidable. The typical result of violations of the three criteria above is an underestimation of *G*. Recent studies have found that commercially available heat flux plates underestimate *G* from 2% to 73% in the laboratory (Sauer et al., 2003, 2007) and from 18% to 66% in the field (Ochsner et al., 2006). The data in Figure 9.10a illustrate the underestimation, which is typical of soil heat flux plates. These data show that the magnitude of *G* at a 5 cm depth


FIGURE 9.10 Soil heat flux at 5 cm (G_r) under corn as measured by heat flux plates (REBS HFT1.1) shown in (a) and the single-probe gradient method (b) versus the three-needle gradient method. The solid lines are the regression lines, and the dashed lines are the one-to-one lines. (Reprinted from Ochsner, T.E., T.J. Sauer, and R. Horton. 2006. Field tests of the soil heat flux plate method and some alternatives. Agron. J. 98:1005–1014. With permission. American Society of Agronomy.)

was underestimated by ~26% using some of the best available soil heat flux plates. Some other commercially available plates exhibit significantly worse performance (Ochsner et al., 2006).

Two primary alternatives to the traditional soil heat flux plate method are the three-needle gradient method and the self-calibrating plate method. The gradient method typically employs a three-needle HP sensor capable of measuring the ambient soil temperature gradient and soil thermal conductivity (Cobos and Baker, 2003; Ochsner et al., 2006). Soil heat flux is then calculated directly from Equation 9.7. This three-needle gradient method has produced excellent results in field tests (Cobos and Baker, 2003; Ochsner et al., 2006). Figure 9.10b illustrates the performance of the three-needle gradient method by comparing it to an independent single-probe gradient method. The magnitude of G at 5 cm measured by these two methods agrees to within ~6%. The three-needle gradient method offers additional benefits in that soil temperature, thermal properties, and water content can be obtained simultaneously with the same sensor. The method has been recently extended to measuring G under freezing and thawing conditions (Ochsner and Baker, 2008).

The self-calibrating plate method uses a soil heat flux plate to which a film heater is added on the upper face. The plate violates the three criteria identified in the first paragraph of this section; however, by introducing a known heat flux via the heater at predetermined intervals (e.g., 3 h), an in situ calibration constant is obtained that varies with the soil conditions. The procedure results in more accurate soil heat flux data than the traditional plate method (Ochsner et al., 2006). Increased adoption of the three-needle gradient method and the self-calibrating plate method should lead to more accurate soil heat flux and surface energy balance data.

9.7.2 Interpreting Soil Heat Fluxes

It has been suggested that a sensible heat balance offers a means to track the soil evaporation front within the soil (Gardner and Hanks, 1966; Mayocchi and Bristow, 1995). Evaporation of soil water represents a large heat sink. A sensible heat balance is used to determine the amount of latent heat involved with vaporization of soil water following Gardner and Hanks (1966):

$$(H_0 - H_1) - \Delta S = LE \qquad (9.32)$$

where
  H_0 and H_1 are soil heat fluxes (W m^{-2}) at depths 0 and 1, respectively
  ΔS (W m^{-2}) is the change in soil sensible heat storage between depths 0 and 1
  L (J m^{-3}) is the latent heat of vaporization
  E is evaporation (m s^{-1})

Using measurements of soil thermal conductivity (λ, W m^{-1} °C^{-1}) and the temperature gradient (dT/dz, °C m^{-1}), values for H can be determined from Fourier's law (Ochsner et al., 2006). Ochsner et al. (2007) provide several approximations for determining ΔS from measured temperature (T, °C) and soil volumetric heat capacity (C, J m^{-3} °C^{-1}). One approximation is

$$\Delta S = \sum_{i=1}^{N} C_{i,j-1} \frac{T_{i,j} - T_{i,j-1}}{t_j - t_{j-1}} (z_i - z_{i-1}), \qquad (9.33)$$

where
  z (m) is depth
  the subscripts i and j are index variables for depth layers and time steps, respectively

The residual from the energy balance provided by the left side of Equation 9.32 is attributed to LE, which cannot be measured directly. Values for L can be calculated from Equation 9.4 using the soil temperature at the depth of interest. Having values for H, ΔS, and L, it is possible to calculate E from Equation 9.32.

Heitman et al. (2008b, 2008c) placed several three-needle HP sensors at shallow depths in a soil. The central needles of the sensors were positioned at 6, 12, 18, 24, 45, and 60 mm below the soil surface. The plane formed by the three needles

of each sensor was oriented perpendicular to the soil surface. (a) The sensors were connected to a data acquisition system, and HP measurements and soil temperature measurements were obtained each 4 and 0.5 h, respectively. They were able to use their measurements to estimate sensible and latent heat fluxes with depth and time. The latent heat flux estimates allowed them to estimate soil water evaporation as a function of depth and time, thus revealing the temporal patterns of in situ evaporation and condensation. This approach is measurement driven, so it does not require determination of coupled heat and water transfer coefficients (e.g., Nassar and Horton, 1997) or soil-specific hydraulic properties.

Results for a 6 day period are presented in Figures 9.11 and 9.12. Data for the uppermost HP sensor (centered at 6 mm) are

FIGURE 9.12 Evaporation determined by heat balance using HP sensors. Data were collected in 2007 from a bare field in Iowa following rainfall on DOY 172. (Reprinted from Heitman, J.L., X. Xiao, R. Horton, and T.J. Sauer. 2008c. Sensible heat measurements indicating depth and magnitude of subsurface soil water evaporation. Water Resour. Res. 44:W00D05. With permission.)

shown in Figure 9.10. During this time period, daily maximum ambient T generally increases after rainfall through day of year (DOY) 178 at the 0, 6, and 12 mm depths (Figure 9.11). Drying in the upper portion of the soil profile also produces decreases in both C and λ (Figure 9.11). Accompanying these changes are shifts in the magnitude of dT/dz at the 3 and 9 mm depths. The magnitude of dT/dz is similar with depth through DOY 175 (Figure 9.11). On DOY 176, the peak magnitude of dT/dz at 3 mm begins to increase and thereafter remains relatively large. A shift also occurs at 9 mm on DOY 176, but peak magnitudes remain well below those at 3 mm until DOY 178 when the gradients begin to converge. This indicates that the zone of evaporation has moved below 9 mm. Driven by dT/dz, heat flux density demonstrates a similar pattern (Figure 9.11). The 3 and 9 mm deep heat flux densities are nearly identical through DOY 175. However, beginning on DOY 176, divergence in the heat flux density with depth indicates significant heat loss (>150 W m^{-2}) as heat is transferred through the soil. The amount of heat partitioned to ΔS can be quantified and remains consistently small throughout this period (<25 W m^{-2}). The difference between heat flux density at 3 and 9 mm (i.e., G_1 and G_2) appreciably exceeds ΔS through DOY 178 and thereby allows determination of LE with Equation 9.33.

Results for sensors measuring the 3–9, 9–15, 15–21, and 21–27 mm depth increments are shown in Figure 9.12. Note that data are presented as evaporation rate, E (mm h^{-1}), rather than LE. The evaporation rate remains near 0 for all measured depth increments through DOY 175, which indicates that the evaporation zone has not passed below the 3 mm soil depth. All sensible heat transferred through the 3 mm depth is accounted for through ΔS or heat flux density at lower depths. On DOY 176, the peak magnitude of E increases to 0.3 and 0.15 mm h^{-1} during the afternoon at the 3–9 and 9–15 mm depth increments, respectively. The peak magnitude of E continues to increase for both depth increments on DOY 177

FIGURE 9.11 Measurements obtained with HP sensors: T is soil temperature, C is volumetric heat capacity and λ is thermal conductivity, dT/dz is temperature gradient, and G and ΔS are heat flux densities and change in sensible heat storage. Data were collected in 2007 from a bare field in Iowa following rainfall on DOY 172. (Reprinted from Heitman, J.L., X. Xiao, R. Horton, and T.J. Sauer. 2008c. Sensible heat measurements indicating depth and magnitude of subsurface soil water evaporation. Water Resour. Res. 44:W00D05. With permission.)

before declining on subsequent days. Net evaporation rates are generally highest immediately following rainfall, assuming that atmospheric demand is not limiting (Lemon, 1956). Thus, the relatively lower E on DOY 176 than 177 does not necessarily suggest less total evaporation. Rather, it indicates that evaporation is still occurring in the soil layer above the 3 mm depth on DOY 176. Transition to evaporation at deeper soil depths is beginning to occur on DOY 176 as soil water stored above the 3 mm depth is depleted and cannot meet atmospheric demand. After DOY 177, measurements of the 3 mm heat flux density (Figure 9.11) suggest that nearly all evaporation occurs below the 3 mm soil depth. The shifting pattern of evaporation continues on subsequent days as soil water storage is further depleted near the surface and peak E at 9–15 mm begins to exceed E at 3–9 mm (Figure 9.12). The declining peak magnitudes of E for all depth increments after DOY 177 are indicative of decreased total evaporation as soil water becomes limiting.

9.8 Managing the Soil Thermal Regime

Agricultural management practices, including irrigation, drainage, tillage, and crop residue management, have the potential to affect the thermal properties of soils and therefore soil thermal regime. In particular, the effect of tillage and crop residue management on soil heat flux has been the subject of several studies (Allmaras et al., 1977; Pikul et al., 1985; Enz et al., 1988; Azooz et al., 1997; Richard and Cellier, 1998; Sauer et al., 1998). Tillage loosens the surface soil, although some local compaction may also occur. Lower soil bulk density generally translates to lower λ; thus, lower G has been observed in tilled soil as compared to untilled or compacted soil (Azooz et al., 1997; Richard and Cellier, 1998). Tillage can also influence surface energy partitioning through its effects on albedo, emissivity, and near-surface water content.

Crop residues can strongly influence the soil thermal regime. They can shade the soil, increase the shortwave albedo, and change the longwave emissivity of the land surface. Crop residues slow the rate of soil water evaporation and can result in higher soil water content. Water content, in turn, influences soil physical properties and surface energy partitioning. Compared to bare soil, crop residues can reduce extremes of heat and mass fluxes at the soil surface. Managing crop residues can result in more favorable agronomic soil conditions. The quantity, quality, architecture, and surface distribution of crop residues affect soil surface radiation and energy balances, soil water content, and soil temperature (e.g., Bristow, 1988). Crop residue has a low thermal conductivity and, whether lying on the soil surface or incorporated into the soil by tillage, inhibits heat transfer into the soil. Residue layers also have a shortwave reflectivity that is higher than most soils and provide a barrier to vapor flow (Gausman et al., 1975; Horton et al., 1996; Sauer et al., 1997). Thus, soils with a large proportion of the surface covered by crop residue tend to have higher water contents, lower temperatures, and lower G. Such changes in soil thermal regime, of course,

have implications for the surface energy balance and evaporation. Horton et al. (1996) provide a review of crop residue effects on surface radiation and energy balances.

Plastic "mulches" (i.e., plastic film) placed on the soil surface are another method often used to manage the soil thermal regime. Plastic mulches modify the soil thermal regime by changing the radiation budget of the surface and by suppressing evaporation (Ham et al., 1993). Plastic mulches usually result in higher soil temperatures, but the effects of plastic mulch depend on the optical properties of the mulch and on thermal contact resistance between the plastic and the soil surface (Ham and Kluitenberg, 1994).

9.9 Soil Temperature and Global Climate Change

Soil temperature and temperature of underlying geologic formations are strongly linked with global climate. The heat capacity of soil and rock is much larger than that of air; thus, if heat is accumulating on earth, we should expect more heat storage in the soil and rock than in the atmosphere. Baker and Baker (2002) examined a long-term data set of subsurface temperature measurements to quantify subsurface heat accumulation. They found an average annual downward flux of 1.1 MJ m^{-2} at the 1.6 m depth over a 37-year period. At the 12.8 m depth, the average annual downward heat flux was 0.22 MJ m^{-2}. Similarly, Beltrami et al. (2002) found a net downward long-term heat flux at the land surface with a global average of 1.2 MJ m^{-2} annually in the period from 1950 to 2000. Total heat accumulation in the continental lithosphere from 1950 to 2000 (9.1×10^{21} J) exceeded heat accumulation in the atmosphere (6.6×10^{21} J) and was second only to heat accumulation in the world's oceans (182×10^{21} J).

There is evidence that subsurface heat storage is not adequately simulated in general circulation models (GCMs), which are used for climate change projections. Current GCMs have 0 heat flux bottom boundary conditions at depths of between 1.5 and 10 m below the land surface (Smerdon and Stieglitz, 2006). The results of Baker and Baker (2002) indicate that >20% of subsurface heat storage occurs below the 10 m depth; thus, even the GCM with the deepest bottom boundary (ECHO-G, 10 m) may contain significant errors. In a simulation study, a land model with a 600 m deep bottom boundary stored 6.2 times more heat than ECHO-G under Intergovernmental Panel on Climate Change (IPCC) emission scenario A2 (MacDougall et al., 2008). To put this result in perspective, the difference in predicted continental heat storage between the models with shallow and deep bottom boundaries was 8.2×10^{22} J over the period from 1991 to 2100, while the estimated heat accumulation in the atmosphere from 1955 to 2003 was only 0.5×10^{22} J. Neglecting deep-subsurface heat storage in GCMs may lead to overpredicting soil temperature changes, overpredicting ocean- and atmosphere-temperature changes, and misrepresenting a host of atmosphere–land surface feedbacks and linkages. Clearly, a better understanding of the soil thermal regime and its connection with global climate is needed.

9.10 Concluding Remarks

Research to date has produced a rich store of knowledge on the soil thermal regime at scales ranging from the core sample to the field soil profile. This chapter has hopefully served to briefly introduce the key topics and direct the reader to the wealth of available literature. Still, there remain wide frontiers of unexplored phenomena at outlying scales both small (e.g., aggregate, pore, and particle scales) and large (e.g., field, watershed, and continental scales). With the continued advancement of measurement capabilities, there should be no shortage of research possibilities in the ongoing study of the soil thermal regime.

10.1 Sampling a Soil Process

One of the parameters of soil ecosystems are soil processes (Gregorich et al., 2001). Process is based on the Latin word "procedere—to proceed, to advance, to go on." Each individual stage of a process depends on the previous stage in either a causal (deterministic) manner or a probabilistic (stochastic) manner. A soil process can be considered in space and time. A spatial soil process is the change of a variable or a state vector consisting of several variables across a spatial domain caused by underlying effects. The spatial process of soil water content considered across a landscape can be influenced by spatial changes in soil type, topography, vegetation, rainfall, evapotranspiration, management, etc. Similarly, a temporal process is the change of a soil variable or state vector observed at the same location over time caused by underlying effects. The temporal process of soil water content is influenced by temporal occurrences of precipitation, evapotranspiration, drainage, capillary rise, etc. Hence, subsequent stages in either space or time do not vary randomly but depend on each other. If in fact subsequent stages of a process do not depend on each other but rather vary randomly, the monitoring of a sequence of stages would not allow us to derive any causal or statistical relationships between various ongoing changes. In other words, the spacing or time increments between observations would be inappropriate to identify the process.

Sampling a soil process in either the spatial or the temporal domain is different from what soil scientists usually try to achieve when they aspire a "good" average, or a representative mean value for a plot that received a specific treatment, which assures that the status of this plot is different from the one that received a different treatment. Investigating a spatial or temporal process does not require the a priori installation of two or more treatments but is rather focused on measuring gradual changes with a series of observations of a state variable or an ensemble of state variables, called state vector. Monitoring gradual changes implies that changes in the observed variable are smaller between subsequent and neighboring observations than over a long spatial distance or time interval. If changes over short distances or time intervals are indeed smaller than changes occurring over long intervals, the variation is called structured, and a range of representativity pertaining to an individual measurement can be derived. In this case, we can interpolate a value located between two measured points at an unobserved point. If on the other hand the variance observed over the shortest sampling interval is in the magnitude of the population variance, this variation is called random, and any interpolation between two points would not be justifiable. In this chapter, considerations are given to the sampling of a spatial or temporal process, to derive spatial or temporal relationships between different variables, apply coregionalization, develop simple spatial or temporal time series models, and quantify cyclic variation components or fluctuation patterns within data series. Appropriate soil sampling schemes in which investigators aimed to detect variability structure have been widely discussed in the literature. Burgess and Webster (1980), Warrick and Myers (1987), Brus and de Gruijter (1997), Boyer et al. (1996), Buscaglia and Varco (2003) are a few examples from different ecological disciplines. When applied to soil, agronomic and ecological investigations,

none of the analytical approaches presented here requires an experiment with treatments, but on the other hand, does not exclude treatment experiments. A wide variety of geostatistical applications in treatment experiments exists in the literature (e.g., Bhatti et al., 1991a; Mulla et al., 1992; Ball et al., 1993; Mulla, 1993; Bishop and Lark, 2006). Some of these are focused on the removal of underlying spatial soil trends whose impact was large enough to obscure treatment effects (e.g., Wilkinson et al., 1983; Mulla et al., 1990; Bhatti et al., 1991b). And among many others, Raftery (1993) and Van Es and Van Es (1993) have demonstrated the application of state-space models and semivariography, respectively, in experiments with treatments. On the other hand, beneficial experiments in agriculturally related disciplines, especially soil science, do not have to depend on replicated randomized treatments. As pointed out by Collis-George and Davey (1960), though argued in some respects by Barley (1964), plant–soil interactions may be understood better in a few experiments focused on understanding the biogeochemical and environmental controls on biological response. With the study of landscape processes and the application of statistical analyses that do not depend on spatial or temporal independence, alternative management practices can well be identified even without treatment experiments (Nielsen, 1987). Inherent variations of data series can be analyzed regardless of the size or extent of the spatial or temporal domain. For example, techniques are applicable to large scale investigations such as remote sensing or data observed over a decade as well as to the small scale of an x-ray image of a soil thin section or the change of soil water storage over time increments in the order of seconds or less.

10.2 Autocorrelation

The autocorrelation function is a special expression of autocovariance. The latter describes the average product of differences of two observations, $A_i(x_i)$ and $A_i(x_i + h)$, respectively, from the mean of a series $\overline{A}$, while the two observations are separated by a distance, the so-called lag h (Salas et al., 1988):

$$\text{cov}[A_i(x), A_i(x+h)] = \frac{1}{N} \sum_{i=1}^{N-h} [A_i(x_i) - \overline{A}][A_i(x_i + h) - \overline{A}]. \quad (10.1)$$

Normalizing the autocovariance function yields the autocorrelation function (Shumway, 1988):

$$r(h) = \frac{\text{cov}[A_i(x), A_i(x+h)]}{\sqrt{\text{var}[A_i(x)]}\sqrt{\text{var}[A_i(x+h)]}}, \quad (10.2)$$

where the two variance terms in the denominator describe the variance of both arrays of data $A_i(x_i)$ and $A_i(x_i + h)$. For large time series, the product in the denominator equals the variance s_A^2.

For a data set with structured variation, the autocorrelation coefficient $r(h)$ decreases with increasing separation distance between observations until it reaches zero. A data set without any variability structure exhibits zero autocorrelation for all lag intervals

(Warrick et al., 1986). This condition underlies all randomized sampling designs and associated statistical analyses. Regardless whether a data set manifests structured or random variation, at zero lag, $r(h) = 1$, because an observation is perfectly related with itself. Nielsen and Wendroth (2003) illustrated the calculation scheme for the autocorrelation function in detail. Nielsen and Alemi (1989) determined the autocorrelation function not only for static variables but also for a rate variable, that is, water flow rate.

In view of sampling a spatial soil process, the purpose of this paragraph is to apply autocorrelation analysis for the evaluation of soil water content measurements along a 440 m transect in a northeast German moraine catena. Gravimetric soil water content was measured at 40–60 cm soil depth based on auger samples (Wendroth et al., 2006; Robinson et al., 2008). The spatial resolution of measurements is varied in the analysis of measurements. First, samples taken at 40 m distances equally spaced along the transect are considered (Figure 10.1a). No obvious trend exists in the data. In some cases, fluctuations in soil water content from one location to the next are small—about 0.01 g g^{-1} and in other cases, they are large—greater than 0.03 g g^{-1}.

The resulting autocorrelation function is depicted in Figure 10.1b. The immediate drop of $r(h)$ at $h > 0$ reflects the random or unstructured variation of soil water content measurements. Regardless of the length of the transect over which we examine spatial differences in soil water content, these differences remain random. Because the autocorrelation coefficients are nil, a spatial range of representativity does not exist for this sampling scenario. This result implies that soil water content sampled at 40 m distances cannot be spatially interpolated because no structured variation exists. Moreover, soil water content measurements cannot be applied to explain the variation of any other variable, since the spatial domain represented by an individual water content measurement is unknown.

If the samples taken at 40 m intervals along this 440 m transect become part of a longer series of soil water content measurements, that is, over several kilometers or a hundred kilometer or any distance over which large scale influences on soil water content, such as varying soil type etc., become dominant, a structured variation of soil water content may perhaps be identified (Wendroth and Robinson, 2008). In such a case, the autocorrelation length of water content observations would be a multiple of the 40 m lag interval. However, to quantify a correlation length within the domain of the 440 m transect, samples need to be taken at distances closer than 40 m, or the volume of an individual sample would have to be increased substantially or both.

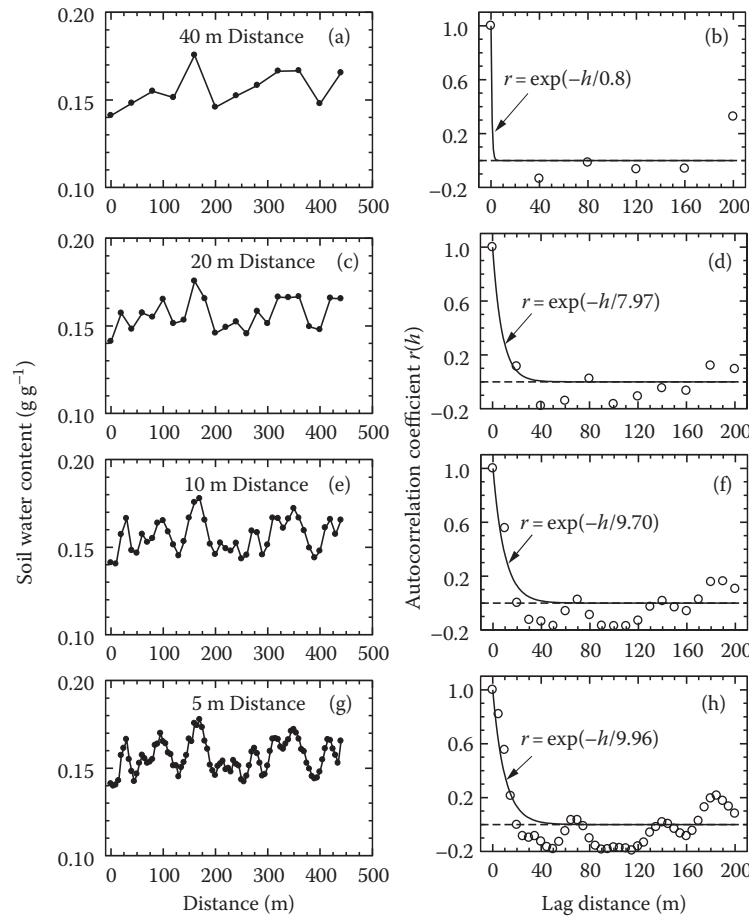
Reducing the sampling distance to one half, that is, 20 m, results in the water content data shown in Figure 10.1c exhibiting a magnitude of local fluctuations close to the magnitude of the average difference between neighboring observations. The corresponding autocorrelation behavior is illustrated in Figure 10.1d. Still, the spatial variation remains random. Hence, even over distances of 20 m, sampling was not close enough to allow spatial interpolation. When the distance between samples was further reduced to 10 m, a more continuous picture of fluctuations in soil water content can be observed (Figure 10.1e). The former peak water content at ~160 m distance in Figure 10.1a is now


FIGURE 10.1 Soil water content measured at the 40–60 cm soil depth across a moraine agricultural landscape in northeast Germany. Measurements are shown for 40 m (a), 20 m (c), 10 m (e), and 5 m (g) sampling intervals. Respective autocorrelation functions $r(h)$ are displayed in (b), (d), (f), and (h).

supported by several values increasing toward that peak value and others decreasing when that peak location is passed (Figure 10.1e). From Figure 10.1a, the investigator could not tell whether this large value at a distance of 160 m was a measurement error, or in fact, a large value belonging to the continuity of the spatial water content process shown in Figure 10.1e. This locally large value gains reliability and represents the process in the context of previous and subsequent observations. The corresponding autocorrelation function depicted in Figure 10.1f manifests the structure of observed variations to a neighboring distance of 1 lag (10 m). By reducing the sampling distance still further to 5 m, the spatial process of soil water content becomes even more obvious (Figure 10.1g), and the autocorrelation function manifests an obvious variance structure. The autocorrelation functions depicted in Figure 10.1f and h imply that samples taken every 10 or 5 m would clearly support spatial interpolation through kriging or other techniques. Samples taken at intervals greater than 10 m would not allow regionalization, at least not in the limited size of this specifically sampled domain.

This brief introduction to the impact of sampling distance on the identifiability of a spatial process is not only relevant for obtaining insight into the representativity of a soil water content

measurement that was generally pointed out by McBratney and Webster (1983), but spatial structure indicated in the autocorrelation function (Figure 10.1f and h) also qualifies a soil water content observation as a covariate for another state variable. This statement is explained in the following paragraph.

10.3 Cross-Correlation

Once the spatial or temporal variation structure and a range of representativity of a variable are identified, its spatial relationship or cross-correlation behavior to another variable can be quantified. This is accomplished through the cross-correlation function $r_c(h)$, which quantifies the relationship between two variables sampled at the same location or time and at different locations with increasing separation distances. Knowing the spatial or temporal variation of two sets of measurements, we can determine from the cross-correlation function how far apart from each other samples can be taken to yield values that remain related with each other (Cassel et al., 2000). This information is especially important in situations where we cannot place two sensors or take soil samples at exactly the same location. The cross-correlation function is also relevant in situations where

two variables cover different spheres of influence, for example, the investigator wants to know whether a point measurement of soil texture is related to an average crop yield measurement taken over an area of 10 m by 10 m.

The cross-correlation function is defined as the covariance of variable A_i sampled at location x_i and variable B_i sampled at a lag interval apart, that is, at $(x_i + h)$, divided by the square root of the product of the variances of both variables (Shumway, 1988):

$$r_c(h) = \frac{\text{cov}[A_i(x_i), B_i(x_i + h)]}{\sqrt{\text{var}[A_i(x_i)]}\sqrt{\text{var}[B_i(x_i + h)]}} . \qquad (10.3)$$

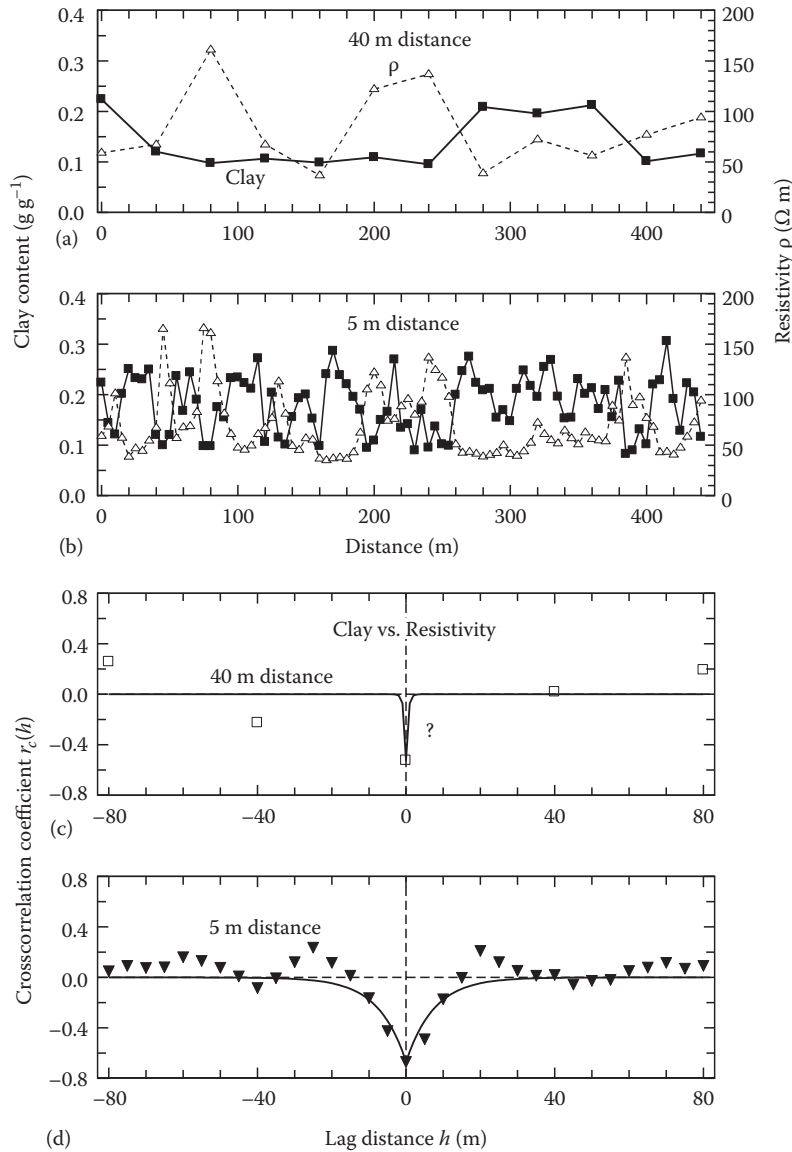
In the same field where soil water content samples had been taken, soil clay content and geoelectrical resistivity ρ were measured at the same 40–60 cm soil depth. Data are presented in Figure 10.2a for a sampling distance of 40 m. From the spatial process of both data series, an inverse linear relationship is derived with a correlation coefficient of $r = -0.505$, given in Table 10.1. Progressively reducing the spatial sampling distances along the 440 m transect from 40 to 20 m, to 10 m, and to 5 m (Figure 10.2a and b, showing only the 40 and 5 m data) not only changes the correlation coefficient between clay content and ρ (Table 10.1), it also has a strong effect on the intercept and the slope of the linear regression (Table 10.1).


FIGURE 10.2 Soil clay content and geoelectrical resistivity ρ measured in a moraine agricultural landscape in northeast Germany at 40 m (a) and 5 m (b) sampling intervals. The cross-correlation functions $r_c(h)$ corresponding to the two sampling scenarios are shown in (c) and (d), respectively, where the question mark in (c) manifests the unknown cross-correlation length.

TABLE 10.1 Linear Regression Equation Coefficients for the Soil Clay Content—Geoelectrical Resistivity ρ Relationship at 40–60 cm Soil Depth and for Different Spatial Resolutions (Sampling Distances *s*)

Sampling Distance *s* (m)	Intercept *a*	Slope *b*	Correlation Coefficient *r*
40	0.183	-5.98×10^{-4}	-0.505
20	0.224	-9.14×10^{-4}	-0.597
10	0.264	-1.318×10^{-3}	-0.679
5	0.266	-1.223×10^{-3}	-0.669

The cross-correlation behavior between both data sets differs for different spatial sampling distances. For the scenario of 40 m sampling distance, observations of clay content and geoelectrical resistivity sampled at 40 m are not spatially cross-correlated (Figure 10.2c, with its "?" manifesting the unknown cross-correlation length) while those sampled every 5 m are clearly cross-correlated (Figure 10.2d). The latter cross-correlation function indicates that a clay content measurement is related to ρ over a distance of 5 to 10 m but not beyond that distance (Figure 10.2d). Notice that the results for different sampling distances are considered over the same domain or extent. The left-hand side of the cross-correlation function reflects clay content leading the ρ series, and the right-hand side ρ leading the clay content series. Leading refers to the way in which both series are shifted against each other for each lag in cross-correlation analysis (see scheme in Nielsen and Wendroth, 2003), that is, lag $h = -1$ refers to the clay series being one position ahead of the ρ series. Before the spatial relationship between two series is examined in cross-correlation analysis, their individual autocorrelation structure needs to be evident. If one or both series are not autocorrelated, their inclusion in a cross-correlation analysis is ineffective.

Analyses obtained for the same pair of variables sampled at different resolution manifests a classical problem in soil science: When soil scientists obtain a regression relationship for two variables over a large scale, such as a database for a pedotransfer function in order to derive soil hydraulic property parameters based on soil texture, the applicability of that information to estimate spatial processes at a smaller scale or resolution is flawed as long as the small scale spatial covariance and cross-covariance remain unknown, ignored, or not even considered. In other words, because the regression relationships changed from coarse to fine measurement resolution, applying the regression equation obtained from the 40 m scale to a smaller scale is invalid. Moreover, the lack of cross-correlation as obvious from Figure 10.2c prohibits any coregionalization of these two variables. Only if the spatial range is known over which one variable is related with the other, a meaningful interpolation or estimation of one variable based on the other can be made for a smaller scale (Lascano and Hatfield, 1992). It is strongly suggested here to include spatial covariance and cross-covariance in the concept of pedotransfer functions, to clearly define data requirements and identify their representativity, validity, and limitation at various scales.

10.4 Semivariogram

The discussion in this section is focused on 1D soil water content data measured along a transect. Indeed, semivariography is not limited to one dimension. It can also be applied in two or three dimensions with directional anisotropy being quantified and included in the analysis and interpretation. What is being said here is valid for studies and data sets that also extend over more than one domain.

In this paragraph, the semivariogram γ(*h*) that is inversely related to the autocovariance is introduced and discussed. Similar to the autocorrelation function *r*(*h*), the relationship between observations taken at locations separated by a lag distance *h* is quantified. Unlike *r*(*h*), the semivariogram is not a normalized form of covariance but is based on absolute differences in the original units in which the variable was measured. The semivariogram is defined as (Vieira et al., 1983; Isaaks and Srivastava, 1989; Journel and Huijbregts, 1991)

$$\gamma(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} [A_i(x_i) - A_i(x_i + h)]^2, \qquad (10.4)$$

where the sum of squared differences between observations separated by a common lag distance *h* is averaged and divided by the specific number of pairs of observations *N*(*h*) in each lag class and divided by 2. In other words, the semivariogram γ(*h*) manifests the average variance between pairs of observations within a given lag distance class.

At this point, we note that in the literature, the term semivariogram is frequently used interchangeably with variogram. Oftentimes, book indices refer to "see variogram" when the reader looks for "semivariogram" (e.g., Isaaks and Srivastava, 1989; Deutsch and Journel, 1997) or vice versa (e.g., Nielsen and Wendroth, 2003). Others, such as Davis (1986) use "semivariogram" exclusively. Cressie (1991) mentions the historical wording and usages of the concept and provides a detailed analysis of various equations used to estimate alternative formulations. Here, we only point out a reason for the difference between the two terms that are related to variance and semivariance owing to the manner in which they are calculated. The variance is the average squared deviation of individual observations from the mean, while the semivariance is calculated from Equation 10.4. The semivariance does not consider the deviation from the mean but is based on the average of squared differences between observations that are separated by a given lag distance. When this average squared difference is divided by 2, it becomes comparable to the variance, since the deviation of either one of the two observations from the mean—as typically calculated for the variance—is half as much as their difference from each other (see Nielsen and Wendroth, 2003).

Hence, the magnitude of semivariance at unstructured variation is similar to the population variance. Although the magnitudes of semivariance and variance may be compared with each other, they are nevertheless based on a different squared deviation or difference. Probably for this reason, the *y*-axis of

a semivariogram is never named "variance" but always "semi-variance" in order to avoid confusion and to refer to its specific manner of calculation. From here on, we shall use the terms semivariance and semivariogram.

In cases where observations show structured variation, $\gamma(h)$ increases with increasing lag distance until it reaches a plateau the so-called sill. The lag distance at which the plateau is reached is called the range. In Figure 10.3a, soil water content observations are shown based on gravimetric soil samples that were taken along a 470 m transect every 5 m in the upper 10 cm of a farmer's field soil in Kentucky. The resulting experimental semivariogram is depicted in Figure 10.4a. Notice, except for $\gamma(h)$ at $h = 5$ m, the semivariance values increase with increasing lag distance until the variance reaches a plateau somewhat above 70 m lag distance. With increasing lag distance, the number of

pairs of neighboring observations separated by lag distance h decreases as shown with the open circles in Figure 10.4d.

Typically, we expect the semivariance to increase with increasing lag distance, and at some distance the semivariance reaches a plateau. Bell et al. (1993), who consider the semivariogram an ecologically relevant measure of environmental structure, question this exception and state that environmental variance may further increase with distance so that environments can be regarded neither as uniform at small scales nor as random at large spatial scales.

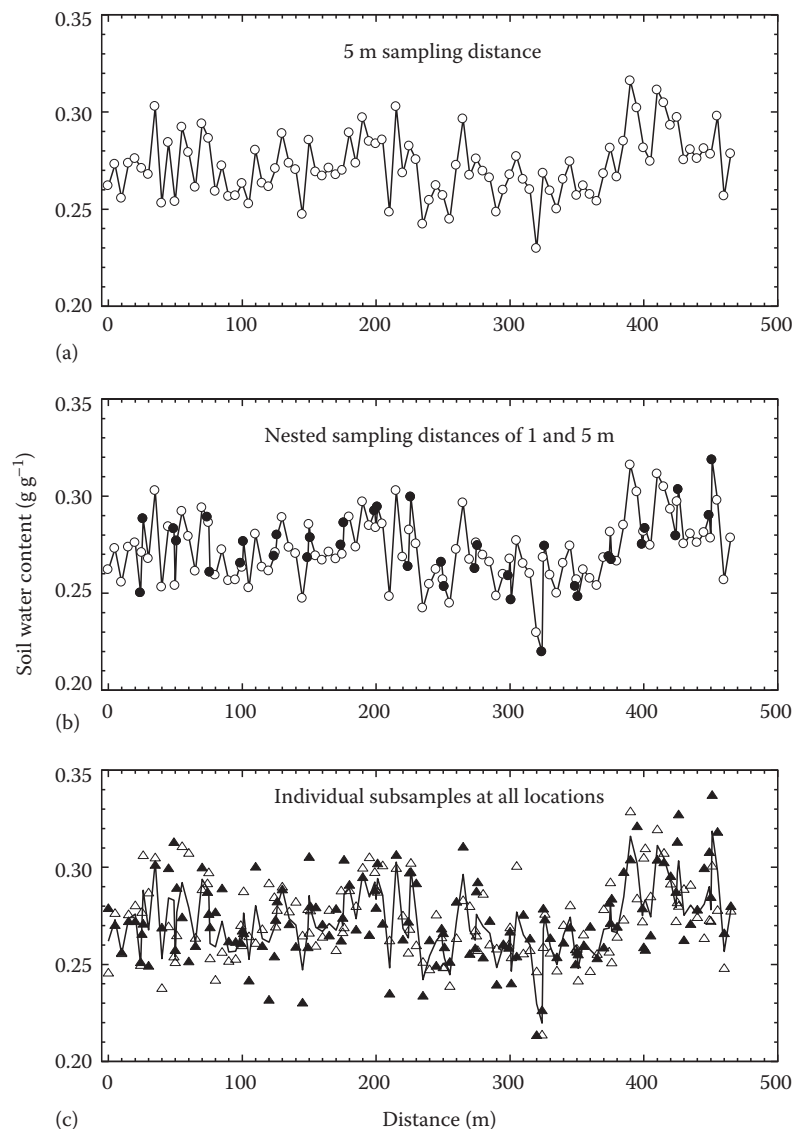
Various types of semivariogram models, shown in detail in Isaaks and Srivastava (1989), Deutsch and Journel (1997), and Nielsen and Wendroth (2003), can be fitted to experimental semivariograms. Typically, a bounded semivariogram model (Nielsen and Wendroth, 2003) consists of a nugget variance C_0 that is the theoretical intercept at $h = 0$, a structural component C, and the


FIGURE 10.3   Soil water content sampled in the upper 10 cm of a silt loam farmer's field soil in Kentucky. Data are shown sampled at every 5 m (a), and in addition at 1 m before and behind the 5 m sampling locations at every 25 m (nested, b). Individual subsamples for all locations are shown in (c) together with the average line from (b).
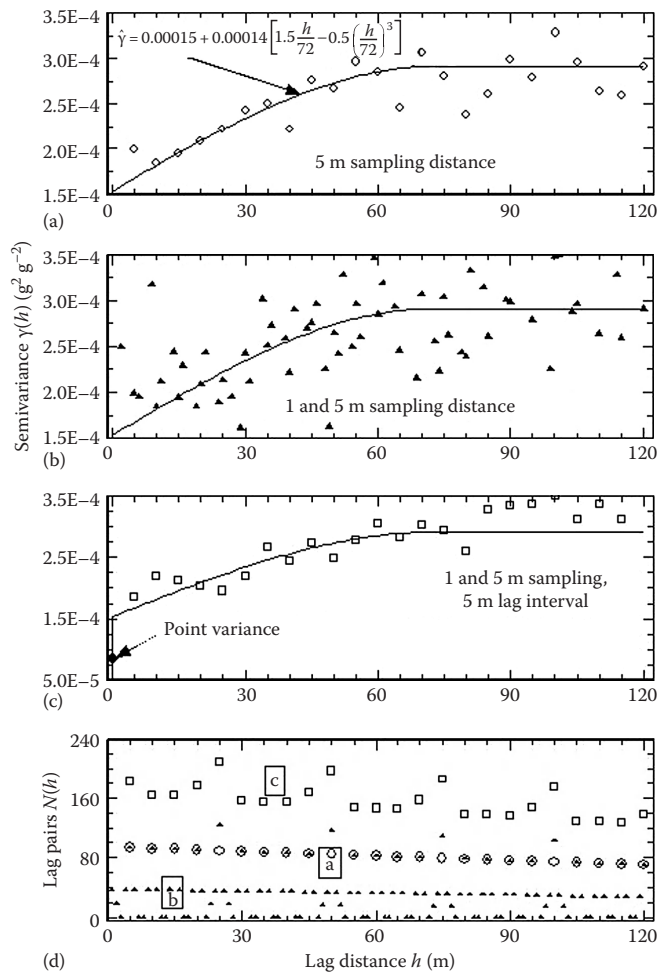

FIGURE 10.4 Spatial variability behavior quantified in semivariograms. Experimental semivariogram and semivariogram model for water content measurements taken at 5 m intervals depicted in Figure 10.3a (a); associated numbers of semivariogram pairs $N(h)$ are shown with open circles in (d). Experimental semivariogram for water content measurements shown in Figure 10.3b at 5 m intervals and at 1 m intervals in nests for 1 m lag intervals (b); associated numbers of semivariogram pairs $N(h)$ are shown with triangles in (d). Experimental semivariogram for water content measurements shown in Figure 10.3b at 5 m intervals and at 1 m intervals in nests but here for 5 m lag intervals (c); associated numbers of semivariogram pairs $N(h)$ are shown with open squares in (d). The filled diamond symbol in (c) refers to the average point variance between duplicate samples taken at each location. Notice the y-axis scale in (c) differing from (a) and (b).

range a, which is the extension of spatial or temporal dependence of observations. The nugget variance represents short-scale variation, sampling, and measurement errors (Isaaks and Srivastava, 1989; Mulla and McBratney, 1999). Nugget and structural semivariance add up to the sill. A spherical semivariogram model was fitted to the experimental semivariogram in Figure 10.4a, where the nugget and sill semivariances are 0.00015 and 0.00014 $g^2\ g^{-2}$, respectively, and the range is 72 m. Most frequently, semivariogram models are used for spatial interpolation using kriging or cokriging. However, semivariogram model parameters provide

the opportunity to compare various data sets with respect to their semivariance behavior, for example, based on the nugget–sill ratio (Cambardella et al., 1994). Notice, when fitting a semivariogram model to an experimental semivariogram for kriging purposes, it is important to obtain a good fit for those lags that carry a substantial weight in the kriging equations (Webster, 1985).

Had the autocorrelation function been calculated for the series of soil water content measurements shown in Figure 10.3a, it would have approximated a vertical mirror image of the semivariogram shown in Figure 10.4a. Unlike the autocorrelation function, the semivariogram displays the semivariance in terms of the square of the original units of measurements. Hence, the investigator is enabled to quantify variance behavior for various separation distances, sampling domain sizes, and sample volumes as well as to compare the semivariance of observations with the variance or uncertainty associated with the measuring device.

Having noted the relatively large nugget semivariance shown in Figure 10.4a to be about 50% of the sill semivariance, the investigator chose a narrower sampling distance to hopefully better define the variability structure at distances <5 m. But it is oftentimes not affordable to regularly sample a long transect at short, for example, 1 m intervals. In this case, every 25 m along the transect two additional soil samples were taken at 1 m distance away from the sampling location within the regular 5 m scheme, as shown with the filled circles in Figure 10.3b. The resulting semivariogram is shown in Figure 10.4b together with the same model as in Figure 10.4a. Since sampling in the nested approach provides 1 m lag intervals in addition to the regular 5 m intervals, $\gamma(h)$ can be calculated for a finer spatial resolution and larger number of lag classes at almost every 1 m interval. Except for multiples of 5 m lag intervals, the number of observed water content pairs present in each lag class is drastically reduced compared to the 5 m sampling scheme to even no pairs of observations separated by specific lag classes, for example, $h = 3, 7, 8, 12, 13$ m, etc. (Figure 10.4d, triangle symbols). The semivariogram depicted in Figure 10.4b is noisier than the one in Figure 10.4a, and its general trend is similar to the one calculated for the 5 m lag intervals. In this case, the nested sampling did not support a more precise quantification of the nugget variance, but confirmed the one obtained from sampling at 5 m distances. One useful conclusion would be that measurements obtained every 5 m could be spatially interpolated or downscaled to 1 m sampling intervals.

Thus, far in this analysis, lag classes were multiples of 1 or 5 m because of either 1 or 5 m distances between sampling locations. Alternatively, a range of lag distances can be included in the same lag class if an upper and a lower bound is defined accordingly. This procedure is especially helpful in designs with nonuniform sampling intervals and for 2D or 3D data sets. Based on the data shown in Figure 10.3b, the semivariogram shown in Figure 10.4c was recalculated for 5 m lag intervals while including all separation distances in-between the 5 m intervals. Hence, the first lag class included all neighboring measurements separated by 1, 2, 4, and 5 m. Increasing the size of lag class intervals is associated with a larger number of pairs of observations per lag class (Figure 10.4d, open square symbols). Again, the same semivariogram

model as in Figure 10.4a and b represents the general trend of the experimental semivariogram with the latter behaving much smoother than in the former cases.

In addition, the investigators evaluated the variance of soil water content at an even smaller scale. Each of the individual samples at every 5 or 1 m, respectively, was composed of two subsamples taken a few centimeters apart from each other. The values of both individual subsamples of soil water content are shown in Figure 10.3c with the same line connecting average water contents at each location as shown in Figure 10.3b. The local point variance existing for a soil water content composed of the two subsamples is illustrated in the semivariogram plot in Figure 10.4c as the filled diamond at $h = 0$. Indeed, this point variance between subsamples is much smaller than the nugget semivariance extrapolated from $\gamma(h)$ at lag distances >1 m. Notice the scale of the ordinate in Figure 10.4c is different than that in Figure 10.4a and b.

A decrease in local semivariance compared to the semivariance prevailing over short distances or from bulk samples is not always observed. Wendroth et al. (2001) and Giebel et al. (2006) found scale-variant behavior of soil mineral nitrogen. Their measurements based on individual small auger samples resulted in a semivariance larger than the nugget semivariance, and only mixing four individual samples taken at the same point and using this bulk sample in spatial analysis allowed identifying a spatial structure of soil mineral nitrogen.

In contrast to the above example, with the exception of taking two or more individual samples at the local scale, had soil water content not been based on gravimetric samples but had been measured with a sensor, the same spatial design and concept to determine variance or error components could have been used. With a sensor used in an access tube or being installed at a fixed point in the soil, readings taken at the same location and depth within sufficiently short-time intervals to exclude temporal soil water content changes could be used to derive the local spatial semivariance of soil water content.

Studying the variance behavior of any state variable, not just that of soil water content, over different distances in space or time, determining the impact of data aggregation on the mean value and its associated variance, and quantifying the instrumental contribution to variance in the way outlined in this example is in general a widely ignored or neglected concept for any type of measurement (Robinson et al., 2008). It is important, however, to make these considerations part of the experimental protocol for determining a spatial or temporal process, for scale transfers of one or several variables, and for spatial or temporal relationships between different variables.

10.5 Kriging

As in the previous section, transect data are used to illustrate the concepts of kriging and cokriging even though these interpolation and coregionalization methods are more frequently applied to 2D and 3D data sets. Kriging is a technique to estimate a value of an observation $A_0^\star(x_0)$ at an unsampled location based on values of the same variable $A_i(x_i)$ observed in the neighborhood of

the unsampled point (Vieira et al., 1981; Trangmar et al., 1985). Based on the spatial relationship between neighboring observations and the distance of these neighboring locations relative to the unsampled location, a weight λ_i is assigned to each of the neighboring observations to contribute to the estimate. The estimated value is the weighted sum of neighboring observations:

$$A_0^\star(x_0) = \sum_{i=1}^n \lambda_i A_i(x_i), \qquad (10.5)$$

where

$$\sum_{i=1}^n \lambda_i = 1. \qquad (10.6)$$

In the kriging algorithm, the weight coefficients are calculated while the difference between the estimated and the true value is zero and the variance between both is at a minimum through

$$\sum_{j=1}^n \lambda_j \gamma(x_i - x_j) + \mu = \gamma(x_i - x_0), \qquad (10.7)$$

where μ is the Lagrangian multiplier. The semivariance values for the respective distance between sampling locations x_i and y_i and between sampling locations and the unsampled location x_i and x_0, respectively, are obtained from a semivariogram model, which is the line fitted to the experimental semivariogram. The minimized kriging variance is calculated with

$$s_k^2(x_0) = \sum_{j=1}^n \lambda_j \gamma(x_j - x_0) + \mu. \qquad (10.8)$$

The set of equations in the kriging matrix is solved for obtaining the weights λ_i and the Lagrangian multiplier μ. Kriging is called the best linear unbiased estimator. Illustrative examples for the setup of the kriging matrix are given in Warrick et al. (1986), Yates and Warrick (2002), and Nielsen and Wendroth (2003).

Kriging, generally used as an interpolation tool, effectively smoothes the process between observed points based on the observed variability structure and its spatial extent. Hence, the kriged distribution of a soil property or a univariate kriged map can support visual assessment of spatial relationships between the variable of interest and any other underlying soil process. On the other hand, unlike other interpolation techniques, such as inverse distances, kriging relies on a spatial variability structure between observations. If that structure is not accurately derived in the semivariogram, subsequent spatial interpolation cannot be trusted. If the method of inverse distances being less rigid than kriging is used in absence of spatial structure, it can lead to fallacious estimates and misleading maps of spatial distributions (Gotway et al., 1996; Kravchenko, 2003) because of lack of underlying variability structure.

Yost et al. (1982a, 1982b) were among the first who derived spatial variability structure of phosphate sorption distribution across
FIGURE 10.5 Soil clay content and geoelectrical resistivity ρ measured along a 440 m transect in a northeast German moraine catena at the 40–60 cm soil depth. Open square symbols depict clay content measured at every 5 m and closed square symbols measured clay content within four nests at 1 m sampling distance. The measurements in the nests were disregarded for the kriging and cokriging estimation scenarios.

a large area and then interpolated unsampled locations based on spatial variability structure in a kriging procedure. Liebhold et al. (1991) mapped moth insect populations based on kriging estimates of spatial distributions. Goovaerts and Chiang (1993) mapped field nitrogen status based on factorial kriging analysis. In a similar fashion, Ghidey and Alberts (1999) mapped soil nitrate concentration based on topography, depth to claypan, and several other underlying variables. Sampling fields without randomized treatments, Donald (1994) mapped weed distributions across landscapes using kriging and pointed out opportunities for new research hypotheses on weed biology and control across landscapes. When applying geostatistical analysis and kriging to attributes that vary over orders of magnitude, indicator kriging can be applied in which spatial distributions of the probability of

an attribute to be below a certain threshold value are interpolated (e.g., Ritzi, 2000). In other applications of indicator kriging, Smith et al. (1993) and Halvorson et al. (1995) combined various indices to map soil quality. Recently, in several approaches, kriging was applied not only in a spatial domain but simultaneously in a spatio-temporal extent (Jost et al., 2005; Cichota et al., 2006).

The soil clay content data considered above from a different perspective (Figure 10.2) are used here again for spatial interpolation by kriging with a slight difference. Besides observations at regular 5 m intervals (open square symbols in Figure 10.5), clay content is known also at 1 m intervals within four nests (closed square symbols in Figure 10.5).

In Figure 10.6a, the experimental semivariogram and the fitted model indicate a range of spatial dependence of 10 m.

$$\hat{\gamma} = 0.0008 + 0.0029 \left[1.5 \frac{h}{10} - 0.5 \left(\frac{h}{10} \right)^3 \right]$$

(a)

(b)
FIGURE 10.6 Kriging scenario: Experimental semivariogram and semivariogram model (nugget + spherical) for soil clay content at 40–60 cm depth (a). Clay content measured at 5 m distances and kriged for 1 m distances (b) along a 440 m transect in a northeast German catena.

The sill proceeds in the order of magnitude of the total variance. It could be argued that the range should extend to a lag distance h of ~15 m, and the sill be somewhat higher. However, in the kriging matrix, only the closest neighbors to the location of estimate are germane. Observations farther than 10 m away from the location of interest do not make a sizeable contribution to the kriged estimate.

The kriging result is depicted in Figure 10.6b. Clay content observations at 5 m intervals were the only information provided to estimate the clay content at 1 m intervals. The filled circles denote the kriged estimates and the gray shaded area the ±1 standard deviation interval around the kriged estimate. As expected, the smooth process of kriged estimates between sampling locations is noticeable. Moreover, because the kriging standard deviation interval increases with increasing distances from sampling locations, it manifests relative maximum values midway between two measured points. We learn from this example that kriging merely interpolates values at unsampled locations based on measurements at surrounding locations. Depending on the change between the observed values—increase or decrease or no change—kriging estimates between two observed values either consistently increase or decrease or do not change at all, respectively, but do not reveal fluctuations at unsampled locations that might in fact exist at a scale smaller than the one chosen for the sampling.

10.6 Cokriging

In many cases of soil surveys and environmental contamination studies, an attempt is made to estimate soil textural or contaminant distribution based on the distribution of another variable that is expected to indirectly reflect the distribution of a particular textural fraction, but is easier and cheaper to monitor. In case of soil clay content, geoelectrical resistivity can be applied as a proxy variable because both variables are spatially related. In spatial studies of contaminants, the distribution of soil pH can help to estimate the distribution of heavy metals in an area (Van Groenigen et al., 1997). McBratney and Webster (1983) cokriged various soil textural particle size fractions among different depths with each other. In various other applications, existing soil landscape models were improved based on using auxiliary variables especially in cases with limited observations (e.g., Vauclin et al., 1983; Alemi et al., 1988; Ben-Jemaa et al., 1994; Chaplot et al., 2000). In many cases of environmental studies in which a variable of interest is coregionalized using cokriging, not all variables are collected at each location, causing only a limited number of common sampling locations contributing to the cross-variogram. In this case, pseudo-cross-semivariograms are a compromise to overcome limited data support for variograms (Zhang et al., 1992, 1999).

The theory and setup of the cokriging matrix are similar to that of the kriging algorithm. Cokriging requires semivariogram models for both individual variables involved in the estimation and the cross-semivariogram $\gamma_{AB}(h)$, which manifests the variance behavior that both variables A_i and B_i have in common:

$$\gamma_{AB}(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} [A_i(x_i) - A_i(x_i + h)][B_i(x_i) - B_i(x_i + h)].$$

(10.9)

In general, the same types of models usually fitted to semivariograms can also be used for describing the cross-semivariogram. The cokriged estimate of a variable $A_0^\star(x_0)$ at an unsampled location is obtained from observations at known locations of both variables $A_i(x_i)$ and $B_j(x_j)$ by

$$A_0^\star(x_0) = \sum_{i=1}^{n} \lambda_{Ai} A_i(x_i) + \sum_{j=1}^{m} \lambda_{Bj} B_j(x_j).$$

(10.10)

The weighting factors for both variables are determined to meet the conditions for A_i

$$\sum_{i=1}^{n} \lambda_{Ai} = 1$$

(10.11)

and for B_j

$$\sum_{j=1}^{m} \lambda_{Bj} = 0.$$

(10.12)

The cokriging matrix is designed as (Yates and Warrick, 2002)

$$\gamma_A(x_{Ai} - x_0) = \sum_{i=1}^{n} \lambda_{Ai} \gamma_A(x_{Ai} - x_A) + \sum_{j=1}^{m} \lambda_{Bj} \gamma_{AB}(x_{Aj} - x_B) + \mu_A$$

$$\gamma_{AB}(x_{Bi} - x_0) = \sum_{i=1}^{n} \lambda_{Ai} \gamma_{AB}(x_{Bi} - x_A) + \sum_{j=1}^{m} \lambda_{Bj} \gamma_{BB}(x_{Bj} - x_B) + \mu_B.$$

(10.13)

The cokriging variance is

$$\sigma_{ck}^2 = \gamma_A(0) + \mu_A - \sum_{i=1}^{n} \lambda_{Ai} \gamma_A(x_{Ai} - x_0) - \sum_{j=1}^{m} \lambda_{Bj} \gamma_{AB}(x_{Bj} - x_0).$$

(10.14)

When fitting semivariogram models with common covariance structure to the two experimental semivariograms γ_A and γ_B, and the cross-semivariogram γ_{AB},

$$\begin{bmatrix} \gamma_{A,1}(h) & \gamma_{AB,1}(h) \\ \gamma_{BA,1}(h) & \gamma_{B,1}(h) \end{bmatrix} = \begin{bmatrix} c_{A,1} & c_{AB,1} \\ c_{BA,1} & c_{B,1} \end{bmatrix} \begin{bmatrix} \gamma_1(h) & 0 \\ 0 & \gamma_1(h) \end{bmatrix}$$

(10.15a)

$$\begin{bmatrix} \gamma_{A,2}(h) & \gamma_{AB,2}(h) \\ \gamma_{BA,2}(h) & \gamma_{B,2}(h) \end{bmatrix} = \begin{bmatrix} c_{A,2} & c_{AB,2} \\ c_{BA,2} & c_{B,2} \end{bmatrix} \begin{bmatrix} \gamma_2(h) & 0 \\ 0 & \gamma_2(h) \end{bmatrix}$$

$$(10.15b)$$

$$\begin{bmatrix} \gamma_{A,3}(h) & \gamma_{AB,3}(h) \\ \gamma_{BA,3}(h) & \gamma_{B,3}(h) \end{bmatrix} = \begin{bmatrix} c_{A,3} & c_{AB,3} \\ c_{BA,3} & c_{B,3} \end{bmatrix} \begin{bmatrix} \gamma_3(h) & 0 \\ 0 & \gamma_3(h) \end{bmatrix}$$

$$(10.15c)$$

the following restrictions apply for the linear model of coregionalization remains positive definite (Isaaks and Srivastava, 1989):

$$c_{Ai} > 0 \quad \text{and} \quad c_{Bi} > 0 \quad \text{for } i = 1,2,\ldots,m \qquad (10.16a)$$

$$c_{Ai}c_{Bi} > c_{ABi}c_{BAi} \quad \text{for } i = 1,2,\ldots,m. \qquad (10.16b)$$

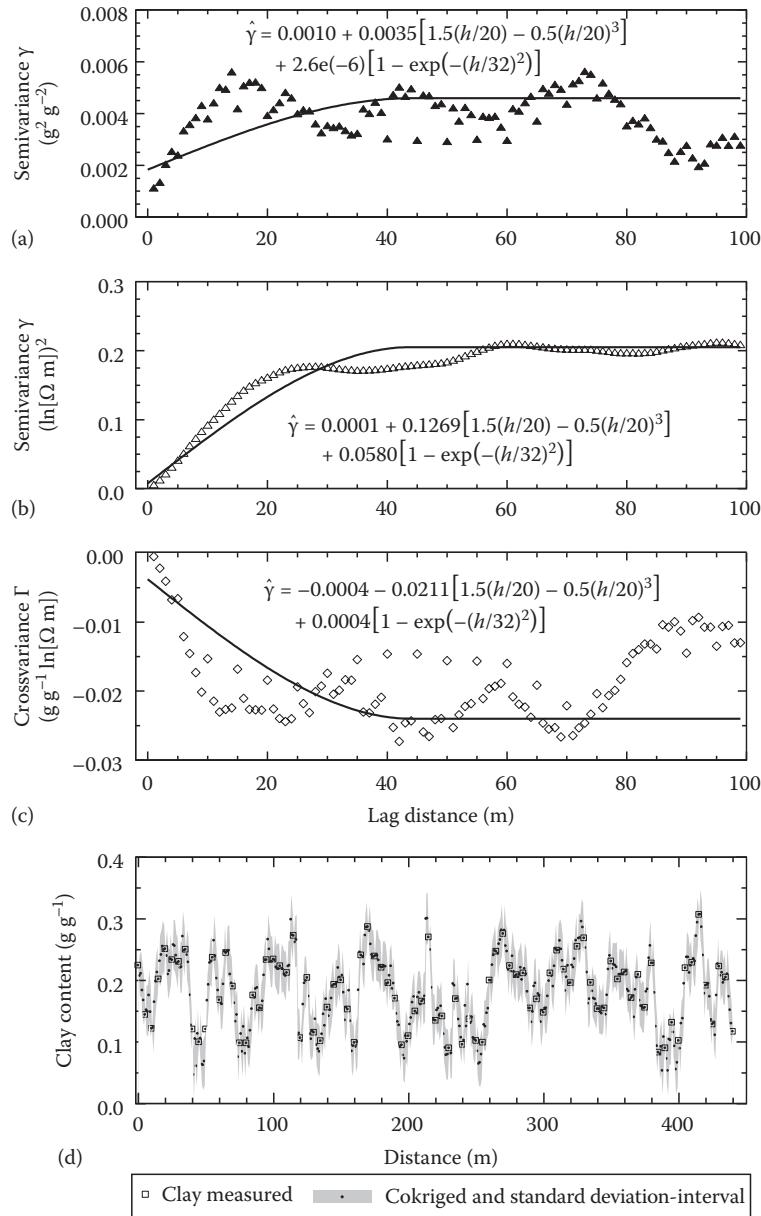
In fact, this restriction causes simultaneous semivariogram and cross-semivariogram model fitting to become a major challenge in the cokriging procedure. In Figure 10.7, the two experimental semivariograms and the common cross-semivariogram for clay content and geoelectrical resistivity $\ln(\rho)$ are shown. Unlike demonstrated in Figure 10.6, where a spherical semivariogram model for soil clay content was derived for kriging, a common


FIGURE 10.7 Cokriging scenario: Experimental semivariogram and common linear model of coregionalization (nugget + spherical + Gaussian) for soil clay content (a), geoelectrical resistivity (b) and cross-semivariogram of both variables (c) measured in a 440 m transect in a northeast German catena. Measured (5 m) and cokriged (1 m) clay content (d).

spherical semivariogram model for clay content and $\ln(\rho)$ that would adequately represent the variability structure of both variables at least for short lag intervals was not identifiable. Instead, a combination of a spherical with a Gaussian semivariogram model consisting of a nugget

$$\begin{bmatrix} c_{A,1} & c_{AB,1} \\ c_{BA,1} & c_{B,1} \end{bmatrix} = \begin{bmatrix} 0.00100 & -0.00037 \\ -0.00037 & 0.00014 \end{bmatrix}, \qquad (10.17a)$$

a spherical component with a spatial range $a_s = 20\,\text{m}$

$$\begin{bmatrix} c_{A,2} & c_{AB,2} \\ c_{BA,2} & c_{B,2} \end{bmatrix} = \begin{bmatrix} 0.00351 & -0.02110 \\ -0.02110 & 0.12687 \end{bmatrix}, \qquad (10.17b)$$

and a Gaussian component with a range $a_G = 32\,\text{m}$

$$\begin{bmatrix} c_{A,3} & c_{AB,3} \\ c_{BA,3} & c_{B,3} \end{bmatrix} = \begin{bmatrix} 2.6e^{-6} & 0.00039 \\ 0.00039 & 0.05797 \end{bmatrix} \qquad (10.17c)$$

resulted in the best common fit of the experimental covariance behavior. The complete set of semivariogram and cross-semivariogram model equations is given in Figure 10.7a through c. These models were applied together with clay content measured at every 5 m (Figure 10.7d) and $\ln(\rho)$ at every 1 m to estimate clay content. Hence, with regard to clay content input data the estimation scenario is the same as in the above kriging procedure (Figure 10.6b), but in addition to clay content, $\ln(\rho)$

and the common covariance behavior between both variables are taken into account in this coregionalization. In general, the standard deviation of the estimated clay content is ~25% smaller in the cokriging compared to the kriging scenario. Unlike kriging, which mainly resulted in a smoothed process of clay content between known locations, fluctuations over short distances become evident in the cokriging results based on the second variable, $\ln(\rho)$, involved in the estimation (Figure 10.7d).

Besides the general process of the series along the 440 m transect estimated with kriging or cokriging, the result is especially interesting with respect to the clay estimation within the four nests, where clay content at every 1 m was known but not incorporated in the estimation procedure. How well did $\ln(\rho)$ capture the clay content process compared to actual measurements? This comparison is illustrated for the first nest, that is, a section of the transect between 35 and 60 m in Figure 10.8.

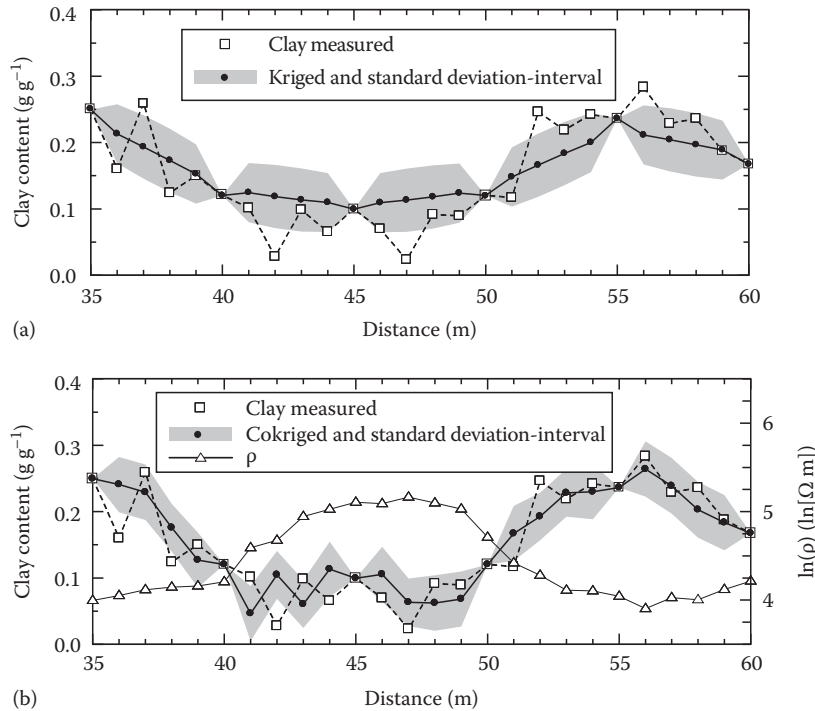
The smooth process of kriged clay content and the relatively large kriging standard deviation are depicted in Figure 10.8a together with measured clay content. On the other hand, cokriging resulted in pronounced fluctuations of estimated clay content. This did not necessarily improve the agreement between measured and estimated clay content from 35 to 39 m, but in most cases between 42 and 49 m, and definitely between 51 and 59 m. In summary, $\ln(\rho)$ and its spatial relationship with clay content helped to improve the clay estimation compared to univariate interpolation, that is, kriging. However, at the finest resolution of 1 m being investigated here, fluctuations in measured clay content do not perfectly coincide with fluctuations of $\ln(\rho)$. This result can be explained by the different domain of influence of an individual measurement of both variables. Clay


FIGURE 10.8 Detailed results of kriging and cokriging scenarios between 35 and 60 m distance depicted in Figures 10.6b and 10.7d.

content samples were pulled with an auger 2 cm in diameter at a depth increment of 20 cm. A single value of geoelectrical resistivity results from the field measurement of apparent geoelectrical resistivity undergoing a numerical inversion, and represents a horizontal domain of ~50 cm, causing the smooth behavior of the ln(ρ) series. Despite lack of sensitivity of clay content fluctuations occurring over 1 m distance, clay content measurements taken every 5 m were successfully downscaled in this coregionalization procedure based on small scale measurements of ln(ρ).

10.7 Autoregressive State-Space Modeling

Requirements for identifying a spatial or temporal process were presented in the previous paragraphs. It became obvious that understanding the spatial process of an observed state variable whose spatial covariance structure is successfully identified strongly depends on its association with other spatial processes. In other words, the question that needs to be addressed is: What other variables coincide with the process of interest across a spatial or temporal domain and how can the association between the variables included in the state vector be described?

Coregionalization using cokriging is a method that is restricted to a common covariance model, that is, a set of semivariograms with common covariance structure. Spatial association between soil variables observed along transects has been derived from autoregressive analysis (Morkoc et al., 1985; Shumway, 1985), a technique that was adapted from time series analysis for spatial data series. Lebron et al. (2007) described the spatial process of soil hydraulic conductivity across a Pinyon-Juniper ecohydrological gradient. In autoregressive models, a variable at a location or a point in time is described based on antecedent observations of the same variable and in case of multivariate autoregressive models on other related variables observed at the previous sampling location (e.g., Wendroth et al., 1992; Nielsen et al., 1994). For a first-order autoregression model, each of the variables measured at the previous location $i - 1$ is linked to the variable at location i through an autoregression coefficient φ or a matrix of autoregression coefficients in case of several variables. A second-order model utilizes antecedent measurements at locations $i - 1$ and $i - 2$, while an n-order model is based on measurements at n previous locations. Coefficients of autoregression are usually estimated in the same way as ordinary statistical regression coefficients. In the particular case of autoregressive state-space models, however, autoregression coefficients are derived in a different way including estimations of measurement and model errors. The set of observations of one or several variables, that is, the observed vector Y_i, does not have to be assumed absolutely correct but consists of the true status of observed variables Z_i and a measurement error υ_i in the observation equation

$$Y_i = M_i Z_i + \upsilon_i, \qquad (10.18)$$

where M_i is a measurement or design matrix.

In the state equation, that is, in this case an autoregression type model, the state vector at location i is related to the state vector at $i - 1$ through the matrix of autoregression coefficients Φ and a model uncertainty ω_i with

$$Z_i = \Phi Z_{i-1} + \omega_i. \qquad (10.19)$$

The advantage of the state-space form of autoregressive models compared to ordinary autoregressive models is the filtering of observational noise, and the fact that the chosen model type and order and the observation vector result in model uncertainty. In other words, the model does not completely capture the spatial or temporal process of the variable of interest. The simultaneous optimization of autoregression coefficients, measurement, and model variance used here is based on the Kalman filter (Kalman, 1960; Kalman and Bucy, 1961) and encoded in the EM algorithm described by Shumway and Stoffer (1982). In the filtering scheme, state estimations and state variance are updated whenever in the spatial or temporal series an observation is available (Katul et al., 1993). This update depends on the model and measurement error and is performed based on a Kalman gain matrix and a recursive smoothing matrix. The filtering scheme is described in more detail in Shumway (1988), Shumway and Stoffer (2000), Katul et al. (1993), Nielsen and Wendroth (2003), and in Webster and Heuvelink (2006). Not only autoregressive but other kinds of equations can be implemented in state-space models. For example, Katul et al. (1993) and Wendroth et al. (1993) used a state-space scheme in connection with a physically based equation describing soil water transport, to estimate unsaturated hydraulic conductivity coefficients from an internal drainage experiment. Parlange et al. (1993) applied a similar approach to estimate soil water diffusivity. Assouline (1993) modeled the hydrologic budget of Lake Kinneret based on state-space analysis of individual water balance components, Skaggs and Mohanty (1998) applied the Kalman filter scheme to describe water table fluctuations, Cahill et al. (1999) estimated field-effective soil hydraulic property coefficients using a physically based state-space model, and Wu et al. (2001) developed a state-space scheme for modeling the water and salinity regime in a soil with a shallow groundwater table. Bierkens et al. (2001) described the space-time development of water table depth based on a Kalman filter approach, and Walker et al. (2002) estimated 3D soil water storage based on surface soil water content measurements implemented in a state-space model. For further details on the state-space concept used in connection with physically based models, the reader is referred to Nielsen and Wendroth (2003).

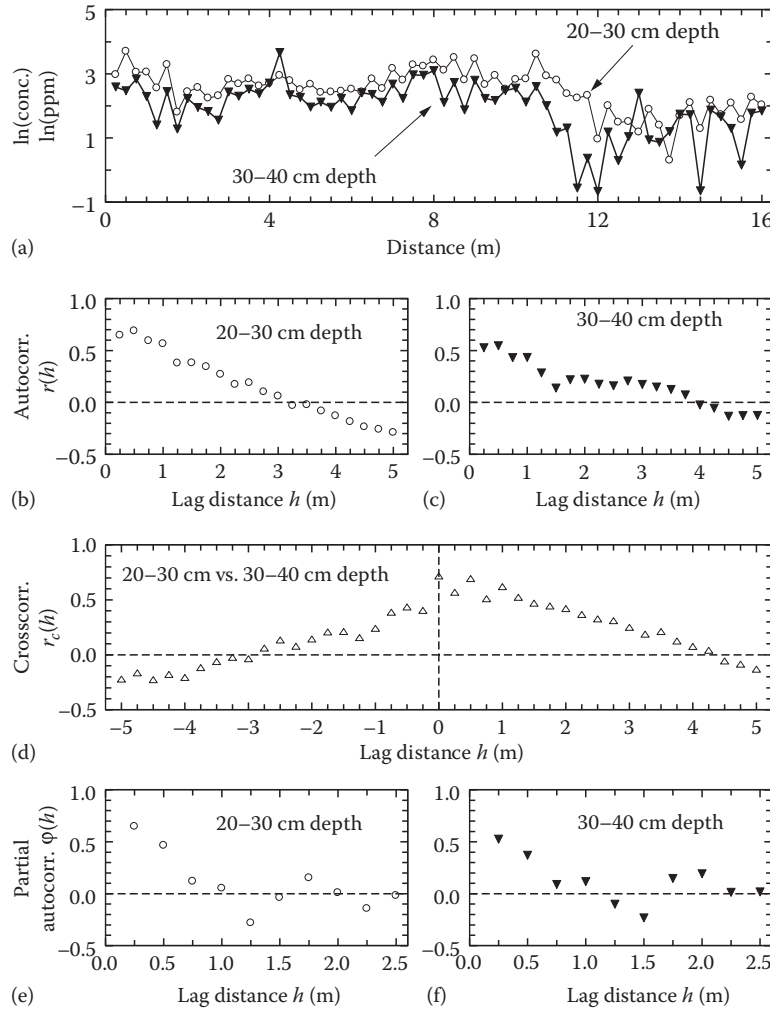
Autoregressive state-space analysis is used here to analyze measured solute concentration data in a field leaching experiment conducted in a Maury silt loam soil in Kentucky. Solute concentration was measured in two subsequent depths (20–30 and 30–40 cm) along a 16 m transect at 25 cm intervals. Logarithmic transforms of solute concentration measured in both depths are shown in Figure 10.9a. Prior to autoregressive state-space analysis, spatial covariance structure of both variables was quantified


FIGURE 10.9 Ion concentration measured at 20–30 and 30–40 cm soil depth in a Kentuckian Maury silt loam (a), autocorrelation functions $r(h)$ at 20–30 cm (b) and 30–40 cm soil depth (c), cross-correlation function $r_c(h)$ between ion concentrations at both depths (d), and partial autocorrelation functions $\varphi(h)$ for the 20–30 cm (e), and the 30–40 cm depth (f).

via auto- and cross-correlation. With both series being spatially autocorrelated (Figure 10.9b and c) and cross-correlated (Figure 10.9d), measurements of solute concentration based on 10 cm long soil samples, ~2 cm in diameter taken every 25 cm provide ample opportunity to monitor the spatial process of solute concentration in both soil layers.

In order to identify the model order of the autoregressive state-space model, the partial autocorrelation function φ_{ii} of order p is calculated with the Durbin–Levinson algorithm (Shumway and Stoffer, 2000)

$$\varphi_{ii} = \frac{r(i) - \sum_{j=1}^{i} \varphi_{pj} r(i-j)}{1 - \sum_{j=1}^{i} \varphi_{pj} r(j)}, \quad i > 1 \tag{10.20}$$

and

$$\varphi_{11} = r(1). \tag{10.21}$$

For $i \geq 2$,

$$\varphi_{ij} = \varphi_{i-1,j} - \varphi_{ii} \varphi_{i-1,i-j}, \quad j = 1, 2, \dots, n-1. \tag{10.22}$$

The resulting partial autocorrelation functions φ_{ii} where the order is expressed as lag distance with $\varphi(h)$ for the solute concentration data of both depths are depicted in Figure 10.9e and f. With the 95% significance level at 0.245, solute concentration data series can be described with a model of the order up to $p = 2$, that is, solute concentration in both layers at location i can be described as a function of solute concentration in both layers at preceding locations $i - 1$ and $i - 2$.

For numerical stability, prior to state-space analysis, observations y_i are normalized (ysc_i) with (Nielsen and Wendroth, 2003)

$$ysc_i = \frac{y_i - (\mu_y - 2\sigma_y)}{4\sigma_y}, \tag{10.23}$$

where μ_y and σ_y denote the mean and standard deviation, respectively, of the particular series.
FIGURE 10.10 First-order autoregressive state-space model of normalized ion concentration at the 30–40 cm soil depth $nc(30)_i$ along a 16 m transect in a Kentucky Maury silt loam soil. Ion concentrations are shown for the 30–40 cm depth [$nc(30)_i$], and concentrations of ions in the 20–30 cm depth [$nc(20)_i$] are included in the estimation. A scenario where all observations are considered is shown in (a) and a scenario where all $nc(20)_i$ observations are included but only every fourth $nc(30)_i$ observation is considered in (b).

Model equations and results for the process of normalized solute concentration at the 30–40 cm layer $nc(30)_i$ are presented in Figure 10.10a for a first-order model in a scenario, where all normalized observations of $nc(30)_i$ and those in the 20–30 cm layer $nc(20)_i$ are included in the model calculations.

Notice that autoregressive models including state-space models depend on equally spaced distances between observations. On the other hand, samples do not need to be taken at each location. Scenarios where one or several variables are observed at each location and one or several other variables at a lower density at, for example, every other location or even less frequent are common. For these missing locations, estimates are obtained in the state-space procedure as shown in the following example.

When only every fourth observation of $nc(30)_i$ is included in the model calculations, the estimated series proceeds smoother (Figure 10.10b) and the 95% interval of estimation is larger than in the previous scenario. Although the value measured at a distance of 4.25 m was considered in the calculations, its extremely high fluctuation was not captured in the model. The second-order model shown in Figure 10.11 results in a better representation of the point-to-point fluctuations than the first-order model. Additionally, the confidence interval of estimation remains narrower for the second-order model compared to that of the first order. For both second-order scenarios, the coefficients in the autoregression equations clearly emphasize the larger weight on $i − 2$ neighboring observations compared to the $i − 1$ neighbors. In both scenarios, the log likelihood [$−2\ln(L)$] indicates a better model description for the models of second rather than of first order.

10.8 Spectral Analysis

Managing soils and crops with machinery in spatially regular paths may cause repetitive or cyclic patterns in the direction perpendicular to the management operation. Moreover, observing ecologically relevant soil state variables over time often results in sinusoidal patterns of variation, for example, the daily or the annual soil temperature cycle, the annual water cycle, and related variables such as microbial respiration, crop water use, biomass production, transpiration, drainage fluxes, etc. Such a cyclic fluctuation of observations can be described with a sine or cosine wave function or a combination of both. Each wave can be characterized by its magnitude in signal, that is, the amplitude. The amplitude is the distance between the baseline and the maximum of the wave, or it is half of the difference between maximum and minimum of the wave. Furthermore, the length of the wave λ is an important characteristic, which is the inverse of its frequency f. The number of cycles or waves per basic time or spatial distance interval is another important measure to describe a cyclic-data series. Moreover, the start point of a wave is flexible relative to another wave or another series. This shift of the starting point is called phase. Relative to each other, two series can be in phase or out of phase. For further details, see Davis (1986).

From Jean Baptiste Fourier we learn that every continuous single-valued function can be represented by a series of sinusoids. In other words, any observed series can be considered as a combination of many independent sinusoidal curves, all with different cyclic characteristics. Spectral analysis according to Fourier allows filtering the different waves and their characteristics that contribute to the observed series, similar to a laboratory analyzer that identifies the compounds of a mixed chemical. Similar to a
FIGURE 10.11 Second-order autoregressive state-space model of normalized ion concentration at the 30–40 cm soil depth $nc(30)_i$ along a 16 m transect in a Kentucky Maury silt loam soil. Ion concentrations are shown for the 30–40 cm depth [$nc(30)_i$], and concentrations of ions in the 20–30 cm depth [$nc(20)_i$] are included in the estimation. A scenario where all observations are considered is shown in (a) and a scenario where all $nc(20)_i$ observations are included but only every fourth $nc(30)_i$ observation is considered in (b).

chromatogram that is obtained from such an analysis in the so-called power spectrum, the individual variance components of the observed series are depicted. Unlike an ANOVA where the statistical influences and significance of different factors and their interactions are separated, spectral analysis decomposes the individual cyclical variance components of a series, their wavelength or frequency, and their contribution to the overall variance. The power spectrum $S(f)$ is defined as

$$S(f) = 2 \int_{0}^{\infty} r(h) \cos(2\pi\, f h)\, dh, \qquad (10.24)$$

which is an integrated form of the autocorrelation function. Hence, in a power spectrum, the presence of a cyclic component is manifested by a peak corresponding to its specific wavelength or frequency. The lag distance corresponding to the full length of its cycle is the corresponding wavelength in the power spectrum. For more details, see Bazza et al. (1988), Shumway (1988), and Nielsen and Wendroth (2003). Sisson and Wierenga (1981) decomposed the spatial variance of steady-state infiltration rates into cyclic components. Folorunso and Rolston (1985) analyzed cyclic relationships between soil properties and denitrification gas fluxes using spectral analysis. Kachanoski et al. (1985a, 1985b) identified frequency dependence of soil microtopography and thickness of A and B horizons. Nielsen et al. (1983) derived how different micrometeorological impacts that would inhibit a uniform interpretation of plant canopy temperature and soil water content measurements can be decomposed by cospectral analysis. Böttcher et al. (1997) showed in a German pine stand that the spatial variability of groundwater chemistry was related to a cyclic solute input pattern at the surface. Timlin et al. (1998) identified similar frequencies for curvature and grain yield spectra in a

farmer's field grown to corn. Wendroth and Nielsen (2002) found frequency-based variations of soil water content and concomitant leaching of a chloride tracer associated with soil tillage operations. The effect of tillage- and traffic-induced changes in soil structure was investigated by Roseberg and McCoy (1992) using spectral techniques. Domsch and Wendroth (1997) discovered cyclic variation of soil structure and penetrometer resistance caused by the management effect of soil tillage with varying intensity.

In Figure 10.12a and b, two cyclic series are given, both based on sine or cosine waves. Series x_1 (Figure 10.12a) is a wavelet consisting of waves of different length and amplitudes, which will be explained in the next paragraph. Series x_2 (Figure 10.12b) consists of 3.5 sine waves, each being 64 observations long. The sum of both series results is series x_3, shown in Figure 10.12c.

The power spectrum of series x_3 as a function of frequency f is shown in Figure 10.13. Inasmuch as frequency is inversely related to wavelength or lag distance of a particular cycle, as the position of a peak in the graph moves from left to right, it represents a variance component based on a cycle of decreasing wavelength or lag distance. Hence, the peak observed at a frequency $f = 0.016$ corresponds to a wavelength of 64, which reflects the sine wave of series x_2 shown in Figure 10.12b whose length is 64 observation points. The other three peaks corresponding to a wavelength of 6.7, 5.5, and 4.5, respectively, are caused by the cyclic components of series x_1. Notice that none of the peaks based on series x_1 approach the magnitude of the peak based on series x_2. The sine wave is the dominating process, whereas the cyclic components of process x_1 cause fluctuations smaller in magnitude. During spectral analysis, the resolution of the power spectrum, that is, the number of wavelengths for which the power spectrum is calculated has to be determined. Depending on the resolution of the frequency range, the number of spectral estimates must be chosen as a power of 2. The statistical significance of a peak in
FIGURE 10.12 Series of Morlet wavelets x_1 (a), of sine waves x_2 (b), and the sum of both denoted as process x_3 (c).
FIGURE 10.13 Power spectrum for process x_3 depicted in Figure 10.12, which is the sum of a set of Morlet wavelets and a sine wave.

the power spectrum can be quantified based on the *F*-statistics of the spectral variance decomposition, which is not described here. For further details see Bazza et al. (1988), Shumway (1988), and Wendroth and Nielsen (2002).

Two sets of data measured in a farmer's wheat field in Kentucky are shown in Figure 10.14. Wheat grain yield was obtained with an automated combine harvester yield mapping system, and the normalized difference vegetation index (NDVI) was measured in spring time with an active laser-induced canopy reflectance

sensor, known as Greenseeker. Both data series were measured along a transect, and sensor data aggregated over a width of 10 m and a length of 5 m. The most pronounced cyclic variation components underlying the wheat yield and the NDVI data occur at a frequency $f = 0.035$, corresponding to a wavelength of 29 observations. The distance of 29 observations taken at 5 m intervals matches almost perfectly to 150 m. This distance is the wavelength at which nitrogen fertilizer was applied at continuously varying rates between 0 and 168 kg ha^{-1}—not randomized—in a
FIGURE 10.14 Wheat grain yield and normalized difference vegetation index (NDVI) measured in a 650 m long strip in a farmer's field in Western Kentucky.

sinusoidal pattern in plots of 30 m width and 15 m length along the farmer's field, similar to a study of Shillito et al. (2009). At a band of smaller frequencies $f = 0.016$–0.023 or wavelengths between 43 and 64 observations, that is, 215–320 m whose center is depicted at $f = 0.02$ in Figure 10.15a, a less pronounced cyclic

FIGURE 10.15 Power spectra for wheat grain yield (a) and NDVI (b) measured in a farmer's field in Western Kentucky and presented in Figure 10.14. Cross- and quad-spectra are shown in (c) and the coherency spectrum in (d).

variation component can be identified. Soil differences reaching especially from 180 to 480 m along the transect coupled with long-term cropping history cause this long trend in variation. The peak at $f = 0.0625$, corresponding to a wavelength of 16 observations or 80 m is more pronounced in the NDVI (Figure 10.15b) than in the yield spectrum (Figure 10.15a).

In order to better understand and relate different spatial processes occurring in this field, spectral relationships between two different variables can be identified with joint analysis of both data series using cospectral analysis.

10.9 Cospectral Analysis

As the spectrum is an integrated form of the autocorrelation function, the cross-spectrum $Co(f)$ is an integrated form of the cross-correlation function $r_c(h)$:

$$Co(f) = 2\int_0^\infty r_c(h)\cos(2\pi fh)\,dh. \tag{10.25}$$

For cospectral analysis, the left- and the right-hand side of the cross-correlation function needs to be averaged. In case of the cross-spectrum, this average accomplished by

$$r_c(h) = 0.5[r_c(h < 0) + r_c(h > 0)] \tag{10.26}$$

yields an even function when both sides of the cross-correlation function are equal. The resulting cosine wave with a maximum at 0, decreases to the minimum at a lag equal to half of the wavelength and increases toward a lag corresponding to the full length of the cosine wave. Hence, the cross-spectrum emphasizes cyclic variations described by a cosine wave. The second component of cospectral analysis is the so-called quad-spectrum. It is based on an averaging of positive and negative lags of the cross-correlation function with

$$r_c'(h) = 0.5[r_c(h < 0) - r_c(h > 0)]. \tag{10.27}$$

The quad-spectrum defined as

$$Q(f) = 2\int_0^\infty r_c'(h)\sin(2\pi f h)\mathrm{d}h, \qquad (10.28)$$

identifies those common cyclic variations between two series of observations that are delayed or shifted against each other by a quarter of a wavelength. This odd function emphasizes cyclic variations that are described by a sine wave.

For two series that yield a symmetric cross-correlation function at both sides of zero lag, that is, that are described by a cosine function, the cross-spectrum reflects common cyclic variations whereas the quad-spectrum is zero. On the other hand, common cyclic variation components of two series that are delayed against each other by a quarter period or 90° can be described by a sine function, and the quad-spectrum shows their common frequency components while the cross-spectrum is zero.

The extent of the delay against each other or the phase lag is quantified in the phase spectrum $h_\varphi(f)$ with

$$h_\varphi(f) = \frac{1}{2\pi f}\tan^{-1}\left[\frac{Q(f)}{Co(f)}\right]. \qquad (10.29)$$

The cross-spectrum shown in Figure 10.15c clearly identifies the two strongly pronounced frequencies that the wheat yield and NDVI data have in common. Their physical interpretations have been given above. For the same pair of variables, the quad-spectrum is merely different from zero for all frequencies as both series move along with any lag relative to each other. Hence, no matter what the shift between two series is against each other, the cross- or the quad-spectrum identifies common cyclic variance components. The shift against each other is quantified in the phase spectrum.

Similar to the coefficient of determination in regression analysis of two variables, the value of the coherency spectrum $Coh(f)$ is close to 1 for every frequency at which the two variables $A_i(x_i)$ and $B_i(x_i)$ have common cyclic variation components, regardless of any shift between them. The coherency spectrum is based on the cross- and quad-spectrum and the two univariate spectra:

$$Coh(f) = \frac{Co^2(f) + Q^2(f)}{S_A(f)S_B(f)}. \qquad (10.30)$$

The coherency spectrum for yield and NDVI series is presented in Figure 10.15d and clearly reflects the common cyclic variance behavior of wheat yield and NDVI over the entire range of frequencies. Since both NDVI and wheat yield evidently show common covariance and coherence, their statistical relationship can be used to predict yield based on NDVI measurements.

It is important to notice that for spectral analysis, sampling distances need to be uniform. The sampling frequency needs to be designed large enough to sufficiently cover the shortest wave component that is expected to cause variability in an experiment, that is, at least four observations per cycle should be taken to avoid under sampling the spatial process.

10.10 Wavelet Analysis

As illustrated and discussed in the previous paragraph, spatial and temporal data series can consist of fluctuations over short or long distances and reflect trends, periodic fluctuations, etc. (Grinsted et al., 2004). Very often, different components of fluctuations underlie each other. In the previous paragraph, periodic oscillations that can occur in a repetitive manner were identified for uni- and bivariate data sets using spectral and cospectral analysis, that is, frequency domain-based techniques. Another analytical technique that decomposes cyclic variations of a data series is wavelet analysis. Unlike spectral analysis, wavelet analysis detects segments within a data set that consist of cyclic fluctuations but that do not necessarily repeat regularly over the entire data set. A wavelet spectrum therefore indicates where in the data set such a fluctuation occurs and over what scale it extends.

Basic ideas and simple applications of wavelet analysis are discussed in this paragraph. The more interested reader is referred to Torrence and Compo (1998), Grinsted et al. (2004), Lau and Weng (1995), and especially the work of Shu et al. (2008), Si (2003), and Si and Farrell (2004) who applied uni- and bivariate wavelet analysis to identify spatial relationships between soil textural and soil hydraulic property information. Wavelet analysis was applied by Lark and Webster (1999) to detect spatial changes in soil type. In this analysis, the continuous wavelet transform is used. Alternatively, the discrete wavelet transform may be applied, which can be considered as a subsampling version of the continuous wavelet transform (Shu et al., 2008). To be applicable in wavelet analysis, the data set needs to consist of equally spaced observations in space or time. Prior to wavelet analysis, a basic or "mother" wavelet shape is chosen, for example, Haar or Daubechies (Nievergelt, 1999; Walker, 1999; Boggess and Narcowich, 2001), Morlet, Paul, or Derivative of Gaussian (DOG) (Torrence and Compo, 1998), and Mexican Hat (Lark and Webster, 1999). The choice of the basic wavelet depends on the nature of the data and the kind of information expected to be extracted or filtered by the analysis. In the wavelet estimation algorithm, this basic shape of the wavelet is moved across the data series and fitted to individual segments of the series, while it is "stretched" in length and amplitude to fit the subset of data as close as possible. Hence, the amplitude or magnitude of the signal and the length scale over which a given wavelet fits a section of a data series are both flexible. Unlike spectral analysis, the result of wavelet analysis is not a periodogram that manifests repetitive patterns of the data in one peak at a given frequency or frequency band. A wavelet spectrum displays the segment of the data series exhibiting wavelet-like fluctuation. It shows where within the data series the fluctuation occurs, over what length scale it extends, and how much it contributes to the overall variance. Hence, the *x*-axis of the wavelet spectrum is the same as

the *x*-axis of the data series, that is, distance in time or space. The *y*-axis represents the scale given in the original sampling units over which the fluctuation expands.

From the various wavelet shapes, a Morlet wavelet is chosen here, which is a plane wave modulated by a Gaussian (Torrence and Compo, 1998) because it allows a good balance between space and frequency localization (Shu et al., 2008)

$$\psi_0(\eta) = \pi^{-1/4} e^{i\omega_0\eta} e^{-\eta^2/2}, \tag{10.31}$$

where

η is the dimensionless time parameter
ω_0 the frequency, here equal to 6

Expressing the complex exponential term containing the imaginary number $i = \sqrt{-1}$ as

$$e^{i\omega_0\eta} = \cos(\omega_0\eta) + i\sin(\omega_0\eta) \tag{10.32}$$

the Morlet wavelet is the sum of a cosine curve (its real part) and a sine curve (its imaginary part).

In Figure 10.16a, a series x_4 consisting of five wavelets is given. Each of the first four wavelets is extended over a length of 27 points. The fifth wavelet reaches from 109 to 216 distance, and its maxima and minima are reduced by a factor of 3 compared to the first four wavelets.

Here, only the continuous wavelet transform $W_n(s)$ is presented. Based on the inverted discrete Fourier transform, the wavelet transform of a series X_i ($i = 1, \ldots, N$) with uniform sampling distance δx is defined as the convolution of X_i as (Torrence and Compo, 1998; Grinsted et al., 2004; Shu et al., 2008)

$$W_i(s) = \sqrt{\frac{\delta x}{s}} \sum_{j=1}^{N} X_i \psi \left[(j-1)\frac{\delta x}{s} \right], \tag{10.33}$$

where the wavelet scale *s* denotes a complex conjugate. At each scale, the wavelet is normalized in order to be comparable to wavelets at other scales and in other series. Further details on the normalization of wavelet functions are explained in Torrence and Compo (1998). With increasing scale the length of the base wavelet increases. Hence, the wavelet coefficient, that is, the weight over a wavelet domain depends on the location and the length of the wavelet. Since the sum of these weights over the wavelet domain always adds up to unity, the wavelet coefficients reflect the variation of samples. The larger the scale of a wavelet becomes, the higher is the edge artifact. For this reason, the cone of influence (COI) is introduced (Grinsted et al., 2004).

Similar to cospectral analysis, the cross-wavelet spectrum reflects areas of high common fluctuations at the same location and across the same scale. The cross-wavelet spectrum is defined as

$$\left| W_i^{XY}(s) \right| = \left| W_i^Y \overline{W_i^X(s)} \right|, \tag{10.34}$$

with

$\overline{W_i^X}$ being the complex conjugate of W_i^X
W_i^{XY} the local relative phase between X_i and Y_i

The normalized form of the cross-wavelet spectrum is the wavelet coherence, indicating the measure of correlation of two series at different resolutions. In its squared form and applying a smoothing operator *S*, the wavelet coherence is defined as (Shu et al., 2008)

(a)

(b)
FIGURE 10.16 Series x_4 consisting of four short Morlet wavelets between distances of 0 and 115, and one stretched Morlet wavelet reaching from 120–210 distance with a smaller amplitude (a). The corresponding wavelet spectrum is presented in (b) with contours reflecting data fluctuations, their scale (period), and their location along the series. The COI is depicted.
FIGURE 10.17   Wavelet spectrum for process x_3, shown in Figure 10.12c.

$$R_i^2(s) = \frac{\left|S(W_i^{XY}(s)s^{-1})\right|^2}{S\left(\left|W_i^X(s)\right|^2 s^{-1}\right) S\left(\left|W_i^Y(s)\right|^2 s^{-1}\right)}. \qquad (10.35)$$

The smoothing operator depends on the base form of the wavelet. For further details see Torrence and Webster (1999) and Si and Zeleke (2005).

The continuous wavelet transform of the process x_4 is shown in Figure 10.16b. As expected for this illustrative example, in the six-point wavelength band, the four basic wavelets cause pronounced signal contours between distances of 0 and 110. At a different wave band reaching over an extent between 16 and 32 points, a less pronounced peak or signal contour manifests the smaller variance of the individual longer wavelet. The contour of the signal is stretched according to the more extended range of the basic Morlet wavelet in the observed series. The area covered with intensive colors marks the above-mentioned COI (Figure 10.16b). Outside this cone, the detection of variance components may be affected by edge artifacts.

The wavelet transform of process x_3 (Figure 10.12c), emphasizes the diagnostic capabilities of wavelet transform analysis as shown in Figure 10.17. At the six-point wavelength band, the eight base wavelets contribute to the variation at their respective locations. At the 64-point band, another pronounced variation component is reflected in the wavelet spectrum. The variation at this band clearly identifies the sine waves, whose wavelength was given with 64 points (Figure 10.12b).

The wavelet spectra for both wheat yield and NDVI data (Figure 10.14) exhibit some common variability features at the 30 m band, at approximately 330 m distance in the transect referring to the transition zone between soil types and cropping history (Figure 10.18a and b). For the 150 m wavelength of nitrogen fertilizer application pattern, a strong variability influence is evident from the wavelet spectra of both, wheat yield and NDVI. This feature is more pronounced for the NDVI spectrum (Figure 10.18b) than for the yield spectrum (Figure 10.18a), as obvious from the original data.

The cross-wavelet spectrum (Figure 10.18c) emphasizes the common locations of fluctuations especially at the 30–60 m band at ~300–360 m along the transect, the zone where a transition from higher to lower soil quality occurs. In this cross-wavelet
FIGURE 10.18   Wavelet spectrum for wheat yield (a) and NDVI (b) data, both shown in Figure 10.14. The cross-wavelet spectrum is presented in (c).

spectrum, arrows to the right indicate in-phase behavior, and arrows to the left out-of-phase behavior between the wavelet spectra. In Figure 10.19, the coherency wavelet spectrum reflects the strong association between both variables at the 16–30 m band between 300 and 360 m. Moreover, the common variation pattern is present along the entire transect at the 150 m band, manifesting the impact of cyclically varying nitrogen application.

Notice that the wavelet spectrum indicates the local presence of individual variation components, their wavelength band or scale, and their contribution to the variance at that scale. If the base wavelet shape is chosen appropriately, the
FIGURE 10.19 Coherency wavelet for wheat yield and NDVI data shown in Figure 10.14.

wavelet spectrum is a tool eligible to detect a pronounced fluctuation in a data series, its intensity, extent, and local relationship to the fluctuation of another process. On the other hand, if cyclically repeating variation components of one or several series and their phase shift relative to each other need to be identified, power spectrum and cross-spectral analysis are the analytical tools of choice.

Appendix

Data Analysis Software

The computer programs for continuous wavelet transform and wavelet coherence, based on MATLAB®, were provided by A. Grinsted and are available at http://www.pol.ac.uk/home/research/waveletcoherence. Geostatistical analyses for semivariograms, kriging, and cokriging were accomplished with ISATIS (Geovariances). Time series analysis, that is, auto-, cross-, and partial autocorrelation, autoregressive state-space analysis, spectral and cross-spectral analysis were conducted with WINASTSA.

Soil Chemistry

Donald L. Sparks
University of Delaware

SINCE THE FIRST EDITION of the *Handbook of Soil Science* was published in 2000, many changes have taken place in the area of soil chemistry. Global environmental challenges such as climate change, water quality, nutrient management, soil contamination, ecosystem health, and energy sustainability have brought soil chemistry research to the forefront. Because these are complex challenges, they must be tackled in a highly interdisciplinary/multidisciplinary manner over a range of spatial and temporal scales. Thus, soil chemists are increasingly interacting with a wide array of scientists and engineers in multiple fields such as chemistry, biology, physics, geochemistry, engineering, economics, ecology, and environmental policy. The use of highly sophisticated analytical tools, particularly those that are in situ and synchrotron-based, and development of advanced speciation and computational models have provided soil chemists with tools that are indispensable in understanding soil chemical reactions and processes at multiple scales. Accordingly, significant advances have been made in understanding, as never before, the chemistry of soil organic matter, soil solution and solid phase speciation, the kinetics and mechanisms of soil chemical reactions, soil colloidal chemistry, oxidation–reduction, ion exchange, adsorption and precipitation processes and complexes, abiotic catalysis, and soil acidity. Advances in these topics are comprehensively covered in the following chapters.

I am extremely grateful to the authors for their excellent contributions and to the referees who made many helpful suggestions for improvement.

Soil Organic Matter

Jeffrey A. Baldock
Commonwealth Scientific and Industrial Research Organisation

Kris Broos
Flemish Institute for Technological Research

11.1 Introduction

Research pertaining to the organic fraction of soils can be traced back in excess of 200 years. Achard (1786) isolated a dark amorphous precipitate upon acidification of an alkaline extract from peat. The effect of organic matter on soil N fertility (von Liebig, 1840), studies on the use of animal manures for maintaining soil fertility (Lawes, 1861), and the influence of soil and tree species on the development of humus form (Muller, 1887) all demonstrated the importance of organic matter in soil processes. The advancement of organic chemical methodologies and confirmation of the presence of various chemical structures in soil organic matter (SOM) lead to the development of theories that SOM was composed of a heterogeneous mixture of dominantly colloidal organic substances containing acidic functional groups and N. More recently, the polyphenol theory was proposed in which quinone structures of lignin and microbial origin polymerize in the presence of N-containing groups (amino acids, peptides, and proteins) to produce nitrogenous polymers (Flaig et al., 1975).

Early research pertaining to SOM has been reviewed by Stevenson (1994). While alkaline extraction of SOM is still practiced, modern analytical techniques, including solid-state ^{13}C nuclear magnetic resonance (^{13}C NMR) spectroscopy, infrared (IR) spectroscopy, pyrolysis gas chromatography/mass spectroscopy (Py-GC/MS), and x-ray adsorption (XAFS), allow selective probing of SOM chemistry within samples of whole soil. Application of these technologies avoids problems of incomplete extraction, artifact synthesis, and lack of biological significance often ascribed to alkaline extraction procedures. The combination of these techniques with SOM fractionation approaches that are capable of identifying biologically important SOM components has significantly advanced our knowledge of the organic fraction of soils and its dynamics over the last 30 years.

Despite such a long history of research and new methodological and technological advancements, many questions related to the genesis and chemical composition of SOM and its impacts on soil fertility, soil pedogenesis, and soil physical and chemical properties persist today. Many excellent texts and review papers have been written on the topic of SOM. Some of the more recent of these are given in Table 11.1. Table 11.1 is not comprehensive, but rather attempts to provide a starting point for anyone interested in understanding the nature and roles of organic matter in soils.

An examination of terms used to describe SOM and its components in the literature revealed a lack of precise and consistent definitions of what SOM is and what its various component fractions represent. Such a problem exists because of the heterogeneity of SOM with respect to its source, chemical and physical composition, diversity of function, and its dynamic character. As a result, the term SOM has been used to describe all organic

materials found in soil (Stevenson, 1994), all organic materials excluding charcoal (Oades, 1988), or all organic materials excluding nondecayed plant and animal tissues, their partial decomposition products, and the living soil biomass (MacCarthy et al., 1990). As suggested by MacCarthy et al. (1990), it is most important that readers establish how particular authors apply the various terms to fully understand and assess the implications of research findings. The definitions of SOM and its components to be used in this chapter have been derived from several sources (Oades, 1988; MacCarthy et al., 1990; Stevenson, 1994; Baldock and Nelson, 2000). The term SOM is used in this work to refer to the sum of all naturally derived organic materials present, and a series of further terms are proposed to define specific components of SOM (Table 11.2).

With the advent of modern elemental analyzers, quantification of the organic fraction of a soil is now often completed by measuring the amount of organic carbon present in a soil. Although this chapter is devoted to the composition, chemistry, and functions of SOM as well as the factors that define SOM content, where particular research studies have focused on the measurement of

TABLE 11.2 Definitions of SOM and Its Components

Component	Definition
SOM	The sum of all natural and thermally altered biologically derived organic materials found in the soil or on the soil surface irrespective of its source, whether it is living or dead, or stage of decomposition, but excluding the aboveground portion of living plants
Living components	
Phytomass	Living tissues of plant origin. Standing plant components, which are dead (e.g., standing dead trees), are included in phytomass
Microbial biomass	Organic matter associated with cells of living soil microorganisms
Faunal biomass	Organic matter associated with living soil fauna
Nonliving components	
Surface plant residues	Organic debris located on the soil surface typically dominated by pieces of plant residues (also referred to as litter)
Buried plant residues	Pieces of organic debris >2 mm found in the soil matrix collected by sieving
DOM	Water soluble organic compounds found in the soil solution, which are <0.45 μm by definition
POM	Pieces of organic debris 53–2000 μm in size with a recognizable cellular structure that are collected on a 53 μm sieve after complete dispersion of a soil (typically dominated by plant residues)
HUM	Organic materials <53 μm remaining after removal of POM and DOM
Resistant organic matter	Highly carbonized organic materials including charcoal, charred plant materials, graphite, and coal with long turnover times
Additional fractions of organic matter	
Macroorganic matter	Fragments of organic matter >20 μm or >50 μm contained within the soil matrix and typically isolated by sieving a dispersed soil
Light fraction	Organic materials isolated from soils by flotation of dispersed suspensions on water or heavy liquids of densities 1.5–2.0 Mg m^{-3}
Nonhumic biomolecules	Organic biopolymers including polysaccharides and sugars, proteins and amino acids, fats, waxes and other lipids, and lignin
Humic substances	Organic molecules with chemical structures, which do not allow them to be placed into the category of nonhumic biomolecules
Humic acid	Organic molecules soluble in alkaline solution but precipitate on acidification of the alkaline extracts
Fulvic acid	Organic molecules soluble in alkaline solution and remain soluble on acidification of the alkaline extracts
Humin	Organic materials that are insoluble in alkaline solution

soil organic carbon (SOC), the discussion will refer to the results obtained in terms of SOC and not SOM. In most instances, SOC and SOM can be used interchangeably; however, in some instances, it is more appropriate to refer to the organic fraction of soils as SOM rather than SOC. For example, when referring to the nutrient content of the soil organic fraction, it would be most appropriate to use SOM since, by definition, SOC in itself only refers to the carbon present and not the associated nutrients.

11.2 Composition of Soil Organic Matter

Soil organic matter is composed of a vast array of different organic residues ranging in size from simple monomeric molecules through complex polymeric compounds to pieces of plant residue >1 cm in size in agricultural systems and potentially >1 m in forests. Independent of size, individual components of SOM can exist at any point along a decomposition continuum ranging from fresh unaltered materials to highly altered materials bearing little chemical or physical similarity to their original source. Additionally, SOM can exist in a free state or be associated to varying degrees with surfaces of mineral particles or buried within aggregations of mineral particles. Such diversity in physical and chemical properties when combined with the spatial heterogeneity of its distribution within the soil matrix at size scales ranging from micrometer to meter makes studies of SOM composition and function challenging.

Often analytical techniques are applied to the whole organic component of soils resulting in the acquisition of weighted average compositional or behavioral data. Such data may or may not provide an adequate assessment of the potential involvement of organic matter in soil processes. For example, the presence of a small amount of biologically labile organic matter could significantly alter short-term measurements of soil carbon mineralization but not be related to a measure of the total amount of organic carbon present. To better understand the nature of SOM and its roles in soil processes, various schemes have been developed to divide SOM into more homogeneous components and to subsequently conduct separate analyses on the isolated fractions.

11.2.1 Elemental Composition

Carbon accounts for the majority of the mass of SOM; however, oxygen, hydrogen, nitrogen, phosphorus, and sulfur can also make significant contributions. Contents of organic matter in

soils are typically quantified by measuring the gravimetric contents of organic carbon and/or total nitrogen. The traditional factor used to convert gravimetric contents of SOC into SOM is 1.72 (Equation 11.1), which assumes a carbon content of approximately 58% by weight. To obtain estimates of SOM content based on the gravimetric content of nitrogen requires the use of a C:N ratio expressed on a mass basis and typically assigned a value of 12 for agricultural soils (Equation 11.2). Spain et al. (1983) summarized the C:N ratios across 3652 surface horizons from Australian soils and obtained ratios ranging from 5 to 35 across all soil types under a variety of management strategies. Snowdon et al. (2005) obtained values ranging from 6 to 51 for Australian forest soils. Higher C:N ratios would be expected where the organic matter in a soil is dominated by less decomposed pieces of plant debris rather than well-decomposed organic matter. Conversely, where well-decomposed materials dominate, lower C:N ratios would be expected. In a review of global C:N ratios for SOM, Cleveland and Liptzin (2007) obtained values ranging from 1.7 to 25.7 when expressed on a gravimetric basis. Average gravimetric C:N ratios for the entire data set (n = 146), grasslands (n = 75), and forests (n = 55) were 12.2, 11.8, and 12.4, respectively, consistent with the typically assigned gravimetric C:N ratio of 12:

$$SOM\,(g\,kg^{-1}\,soil) = 1.72 \times SOC\,(g\,C\,kg^{-1}\,soil), \qquad (11.1)$$

$$SOM\,(g\,kg^{-1}\,soil) = 1.72 \times C:N\,ratio$$
$$\times\,soil\,organic\,nitrogen\,(g\,N\,kg^{-1}\,soil). \quad (11.2)$$

Although C:N ratios have typically been expressed on a gravimetric basis for soils and plant materials, in aquatic and geochemical sciences, elemental ratios have tended to be expressed on a molar basis. Redfield (1958) recognized that marine plankton maintained an average molar C:N:P ratio of 106:16:1 similar to that in marine water. The presence of such a defined relationship for marine systems has been used to constrain marine net primary productivity (NPP) (e.g., Hecky and Kilham, 1988; Turner et al., 2003), and the recognition of defined elemental ratios in components of terrestrial systems is used to constrain nutrient dynamics within carbon and nutrient simulation models (e.g., the Century model; Parton et al., 1987, 1988). Such relationships have led to the development of the concept of ecological stoichiometry in which it is recognized that variations in molar elemental ratios fluctuate within defined boundaries based on environmental conditions and biochemical requirements of organisms. A trend toward expressing elemental ratios on a molar basis is emerging for SOM. Stevenson (1986) provided an estimate of the molar C:N:P:S ratio of SOM as 107:7.7:1:1. Cleveland and Liptzin (2007) defined average C:N:P ratios of soils obtaining values of 186:13:1 for SOM and 60:7:1 for soil microbial biomass with a tendency for grassland soils to be more nutrient rich and forest soils to be more carbon rich. Further quantification of the variance of these ratios for

different components of SOM (e.g., pieces of plant-residue and well-decomposed materials—see Section 11.1) and particular combinations of soil type and land use will aid the development of more accurate predictions of nutrient cycling and potential responses to alterations in management. In particular, improved definition of the net mineralization of nutrients (i.e., the balance between rates of gross mineralization and immobilization) and release into plant-available pools should be obtained.

Molar ratios of carbon, oxygen, and hydrogen can also provide useful information pertaining to chemical changes that occur during decomposition, heating, or other processes where transformations of SOM take place. One useful representation of C:O:H ratios that appears underutilized in SOM studies is a van Krevelen plot (van Krevelen, 1950) in which molar H:C is plotted against molar O:C. Where the elemental composition of SOM components (biomolecules) can be defined, van Krevelen plots can be used to define the possible compositional space in which a sample must reside and whether there is a prevalence of one component over another. Additionally, the trajectory on a van Krevelen plot associated with changes induced by a process of alteration can give an indication of the associated chemical changes (e.g., dehydration, loss of CO_2, or oxidation, which are all associated with different trajectories). Baldock and Smernik (2002) used a van Krevelen plot to define the extent of alteration of natural organic materials during a heating process. When using van Krevelen plots, it is essential that reliable values are obtained for the molar concentrations of O and H. For soils, the presence of hygroscopic water and alterations to soil mineral components during the heating phase of C, O, and H determinations may introduce errors in measurements of O and H concentrations.

Another useful property of SOM that can be calculated from its molar elemental composition is its oxidation state (C_{ox}). The value of C_{ox} for a given organic molecule of the form $C_xH_yO_zN_w$ can be calculated according to Equation 11.3 in which x, y, z, and w represent the molar percentages of C, H, O, and N, respectively, in the molecule or weighted average molecule in the case of SOM. The values for C_{ox} can vary from −4 to +4 but typically vary between −2.2 and +3 in organic molecules. For example, lipids, carbohydrates, and organic acids have C_{ox} values of −2 to −1, 0, and 0 to +3, respectively (Masiello et al., 2008). C_{ox} values of SOM and its components therefore contain information pertaining to molecular composition, biochemical synthesis pathway, extent of decomposition, and diagenetic history. For example, if C_{ox} values <−1 are obtained, then there is likely to be a preponderance of lipid/aliphatic structures present. Alternatively, if values >1 are obtained, then a high content of carboxylic acids is likely. C_{ox} values between −1 and +1 are less informative as a large range of combinations of different compounds could provide such values. However, C_{ox} values may still be used to constrain predictions of molecular composition of SOM and its components.

C_{ox} is mathematically related to the oxidative ratio (OR), which defines the molar ratio of O_2 consumption to CO_2 emission during decomposition. Organic molecules having positive C_{ox} values do not need as much oxygen for complete mineralization as those with negative C_{ox} values. Based on the assumption

that net photosynthesis occurs via Equation 11.4 with all N being obtained as ammonia, the OR can be calculated from C_{ox} according to Equation 11.5. If the required N is obtained as nitrate or through biological fixation of N_2, Equations 11.6 or 11.7, respectively, should be used to calculate OR (Masiello et al., 2008). Quantification of the OR (and thus C_{ox}) of terrestrial forms of organic matter, including that found in soils, can be used to define the fate of CO_2 emitted to the atmosphere by fossil fuel burning (Randerson et al., 2006):

$$C_{ox} = \frac{2z - y + 3w}{x}, \tag{11.3}$$

$$xCO_2 + \frac{1}{2}(y - 3w)H_2O + wNH_3$$

$$\rightarrow C_xH_yO_zN_w + \left(x + \frac{1}{4}(y - 3w) - \frac{z}{2} \right)O_2, \tag{11.4}$$
$$OR = 1 - \frac{C_{ox}}{4}, \tag{11.5}$$

$$OR = 1 - \frac{C_{ox}}{4} + \frac{2w}{x}, \tag{11.6}$$

$$OR = 1 - \frac{C_{ox}}{4} + \frac{3w}{4x}. \tag{11.7}$$

11.2.2 Chemical/Molecular Composition

A heterogeneous chemical structure and an ability to form strong associations with soil minerals make the chemical characterization of SOM difficult. Two approaches to define the chemical/molecular composition of SOM have been used: (1) chemical extraction or degradative methodologies and (2) modern spectroscopic techniques capable of analyzing SOM in situ. With both approaches, it is essential to gain a full understanding of the methodology being used and possible deficiencies in order to assess how selective and quantitative the applied procedures are and whether there is a potential for creating artifacts. Without such an understanding, it is not possible to make appropriate interpretations of the SOM compositional data obtained.

11.2.2.1 Chemical Extraction and Degradative Methods

Chemical extraction and degradative methods for characterizing SOM use aqueous solutions and organic solvents to liberate SOM components with particular chemical characteristics. One of the most common approaches uses an alkaline extraction followed by acidification (Schnitzer, 2000) of the extract to isolate humic acid, fulvic acid, and humin (see Table 11.2 for definitions). These three fractions should not be considered as discrete compounds, as each will contain a multitude of different chemical structures that can be further fractionated and purified. Criticisms pertaining to the use of alkaline extraction/acid

precipitation to separate soil organic and mineral components include the following:

1. Questions related to the ability of alkaline extractable material to be representative of the composition of the unextracted and entire SOM fraction
2. The apparent lack of a relationship between the biological functioning of SOM and its alkaline extractability based on C and N isotopic tracer studies (Oades, 1995)
3. Incomplete segregation and probable mixing of SOM with different molecular compositions and susceptibilities to decomposition
4. Creation of artifacts (alteration of molecular structure) during the extraction and precipitation procedures

It is acknowledged that in early studies of SOM, separation of soil organic and mineral components was essential to allow selective characterization of the SOM, and that alkaline extraction provided such a capability. However, with the advent of more selective degradation procedures and modern analytical instrumentation that can use intact soil samples, it is suggested that the use of alkaline extractants as a means of characterizing SOM should be avoided where possible.

Many additional methods have been developed based on various extraction or degradative methods considered to be "selective" for particular molecular components of SOM. Hydrolysis with 6 M HCl or methane sulfonic acid has been used to quantify the proportion of SOM associated with proteins, amino acids, and amino sugars (e.g., Friedel and Scheller, 2002; Martens and Loeffelmann, 2003; Appuhn et al., 2004). Hydrolysis reactions with sulfuric acid have been used to quantify the allocation of SOM to carbohydrate structures (e.g., Rovira and Vallejo, 2000; Martens and Loeffelmann, 2002). The proportion of lignin in SOM has been quantified using methods that attempt to either isolate the intact lignin molecule (e.g., Tuomela et al., 2000) or quantify the monomeric species released by breaking the macromolecular structure into its component monomeric species (e.g., Baldock et al., 1997b; Chefetz et al., 2002; Leifeld and Kögel-Knabner, 2005). Various solvent-based procedures have been developed and used to quantify the presence of lipids and lipid-like organic materials in soils (e.g., Poulenard et al., 2004; Rumpel et al., 2004).

Although more specific than alkaline extraction procedures, results derived from these more specific degradation procedures should be considered as approximate due to the potential for incomplete extraction and/or nonselective action. Using a combination of extraction techniques in a "proximate analysis approach" designed to isolate and quantify klason lignin, Preston et al. (1997) demonstrated the presence of a range of nonlignin forms of carbon. Additionally, the use of degradation procedures to quantify SOM components involved in biological processes within the soil matrix may be questionable. As an example, consider a polysaccharide molecule located in a pore on the external surface of an aggregate versus the same molecule buried within a matrix of clay particles. Both polysaccharides may be broken down by a sulfuric acid digestion procedure and

detected by subsequent analyses, but the availability of these two molecules to microbial oxidation as well as their relative contribution to soil function would be expected to vary significantly.

Attempts to use chemical fractionation procedures to allocate SOM to labile and recalcitrant fractions without defined molecular composition have also been made. Hydrolysis with HCl and permanganate oxidation procedures have been proposed to offer such capabilities. With HCl hydrolysis, the proportion of carbon or nitrogen entering the hydrolysates has been considered to be indicative of the biologically labile component of SOM. Both Leavitt et al. (1996) and Paul et al. (2001) found that carbon remaining in the nonhydrolysable fraction of soil subjected to HCl hydrolysis was older than that found in the total SOC fraction prior to hydrolysis. Quantifying the proportion of SOC oxidized in permanganate solutions of increasing concentrations has also been used to define SOC fractions with different biological liabilities (Blair et al., 1995). However, the existence of strong correlations between the amounts of SOC oxidized at each permanganate concentration and total SOC (Lefroy et al., 1993) question the selectivity of this approach toward identifying differentially labile SOC components (Blair et al., 1995; Mendham et al., 2002). Furthermore, Mendham et al. (2002) showed that permanganate oxidizable SOC had little relation to the labile pool of SOC respired over a 96 day incubation period, again questioning the existence of a link between chemical and biological reactivities. The absence of a strong linkage between chemical and biological reactivities and the lack of a clear definition of the chemical nature of the SOC components attacked by each permanganate solution can limit the ability of chemical fractionation techniques to be used as proxies for biologically meaningful fractions of SOC (Baldock, 2007).

11.2.2.2 Chemical Characterization with Analytical Instrumentation

A variety of analytical techniques exist that can be used to characterize the chemical composition of SOM. In this chapter, four techniques that can be used to quantify the chemical nature of SOM in situ will be examined: ^{13}C NMR spectroscopy, analytical pyrolysis, Fourier transform infrared spectroscopy (FTIR), and x-ray spectroscopy. Examples of the chemical information obtained by applying these analytical techniques to SOM are given in Figures 11.1 and 11.2. The forms of analytical instrumentation to be discussed are all complementary and, where possible, efforts should be made to utilize combinations of these methods to confirm and provide additional insight into the chemical composition of SOM.

11.2.2.2.1 *Solid-State Nuclear Magnetic Resonance Spectroscopy*

Solid-state ^{13}C NMR spectroscopy can be used to define the chemical environment around individual carbon atoms in an intact soil sample. The only pretreatments required are drying and then grinding to ensure homogeneity. A typical cross polarization ^{13}C NMR spectrum for a soil is presented in Figure 11.1a. Organic carbon found in different chemical environments can be differentiated on the basis of chemical shift (expressed in

units of parts per million of the applied magnetic field). Duncan (1987) has presented a comprehensive review of the chemical shift values associated with different types of carbon. Solid-state ^{13}C NMR spectra acquired for SOM are typically divided into chemical shift regions indicative of the major chemical forms that individual carbon atoms can take Figure 11.1a. Integration of the signal intensity within each region provides a quantitative indication of the amount of each form of carbon present in a sample, provided signal acquisition from all forms of carbon in a sample is quantitative. Methods now exist to define the level of quantitative detection of carbon within solid-state ^{13}C NMR analyses of SOM (Smernik and Oades, 2000a, 2000b); however, adoption has been limited. ^{13}C NMR detection efficiencies can be improved by the application of hydrofluoric acid (HF) pretreatments to concentrate carbon and remove paramagnetic species (Skjemstad et al., 1994; Schmidt and Gleixner, 2005).

Although the distribution of ^{13}C NMR signal intensity within various chemical shift regions has been used to infer the molecular composition of organic matter in a sample, ^{13}C NMR gives no direct information pertaining how the different types of carbon present in a sample are arranged into molecules. For example, the presence of signal intensity in the *O*-alkyl region (65–105 ppm) is often ascribed to carbohydrates. However, three of the 11–12 carbons found in lignin monomers will also resonate within the *O*-alkyl chemical shift region as will some carbon associated with proteins and lipid/wax materials. To extend the level of molecular information obtained from the application of NMR to natural organic materials, molecular mixing models have been defined (e.g., Hedges et al., 2002; Baldock et al., 2004; Nelson and Baldock, 2005). In this approach, it is assumed that the organic carbon present in a sample can be described as a mixture of biomolecules (endmembers) with defined representative chemical structures. The molecular composition of ^{13}C NMR observable organic carbon is then estimated by defining the mixture of endmembers that minimizes the sum of squares of differences between predicted and measured distributions of ^{13}C NMR signal intensity. Baldock et al. (2004) and Nelson and Baldock (2005) have used this approach to estimate the molecular composition and elemental stoichiometry of organic materials found in a range of terrestrial and aquatic systems.

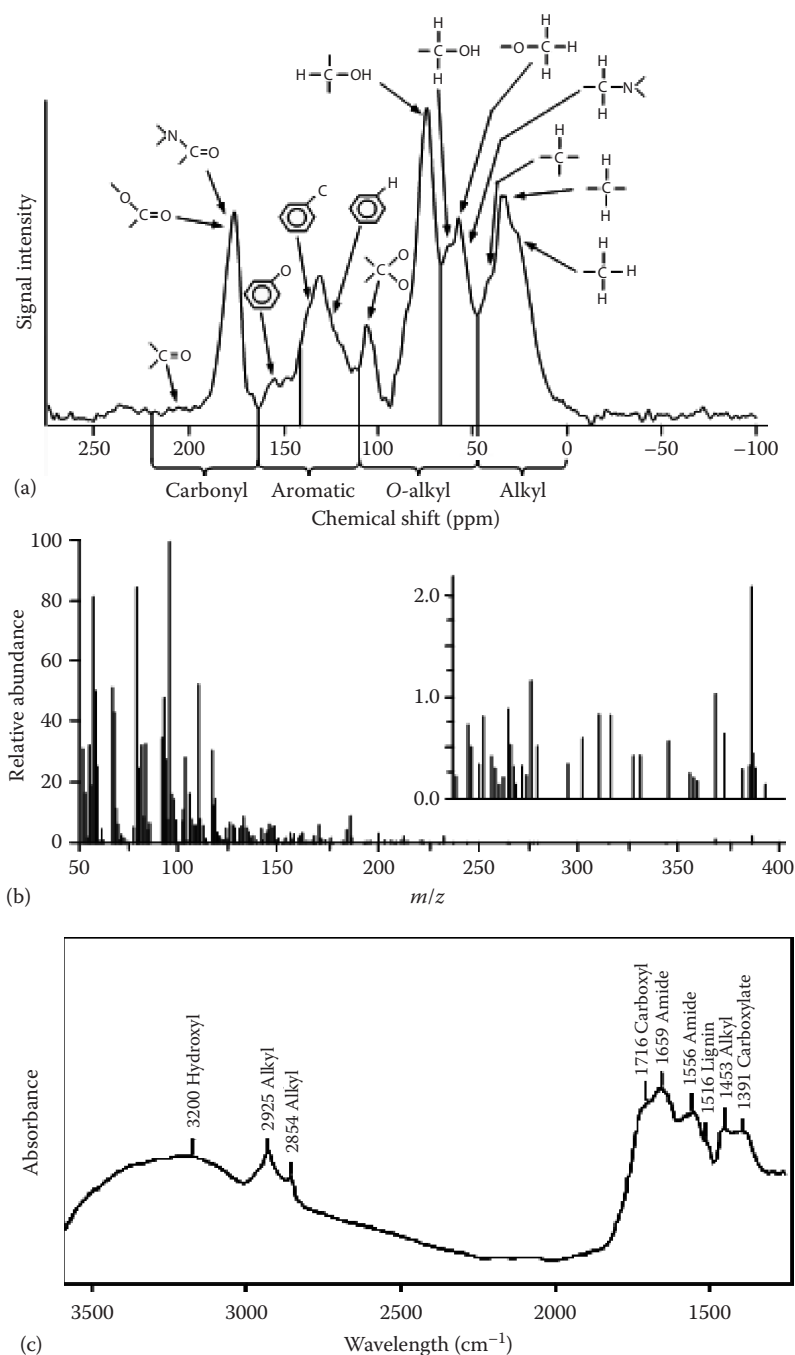
Solid-state NMR has also been used to characterize the chemical composition of organic N in soils (Knicker et al., 1993; Clinton et al., 1995; Knicker and Skjemstad, 2000); however, the low NMR sensitivity and natural abundance of the ^{15}N nucleus make the acquisition of spectra with adequate signal-to-noise ratios difficult. The majority of organic N present in soils is thought to reside in protein (amide) or heterocyclic compounds. In most ^{15}N NMR studies, signals originating from amide structures dominate the acquired spectra, with heterocyclic N structures being detected as a small shoulder on the amide resonance (Mahieu et al., 2000). To improve spectral quality, ^{15}N-labeled plant materials have been used in decomposition and composting experiments (e.g., Knicker and Lüdemann, 1995) with the majority of N again being allocated to amide structures. However, the typical use of short contact times (≤1 ms) and high-field spectrometers (≥300 MHz) have been found to discriminate against nonprotonated heterocyclic N


FIGURE 11.1 Examples of the data obtained from (a) a solid-state ^{13}C NMR analysis of soil humus, (b) a pyrolysis-field ionization mass spectrum of a humic acid (Schulten, 1987), and (c) a diffuse reflectance FTIR spectrum acquired for the 0–2.5 cm layer of a mineral soil (52 g C kg^{-1}) after subtraction of mineral-derived signals.

(Keleman et al., 2002). Smernik and Baldock (2005) applied a spin counting technique to ^{15}N NMR analyses of clay-associated organic matter and found that although the major form of N present was amide, up to half or more of the organic N present must have resided in a form that was insensitive to ^{15}N NMR, potentially heterocyclic N. Careful consideration of ^{15}N pulse programs and the use of spin counting techniques are required to obtain ^{15}N NMR results that are indicative of all N present in a sample of soil.

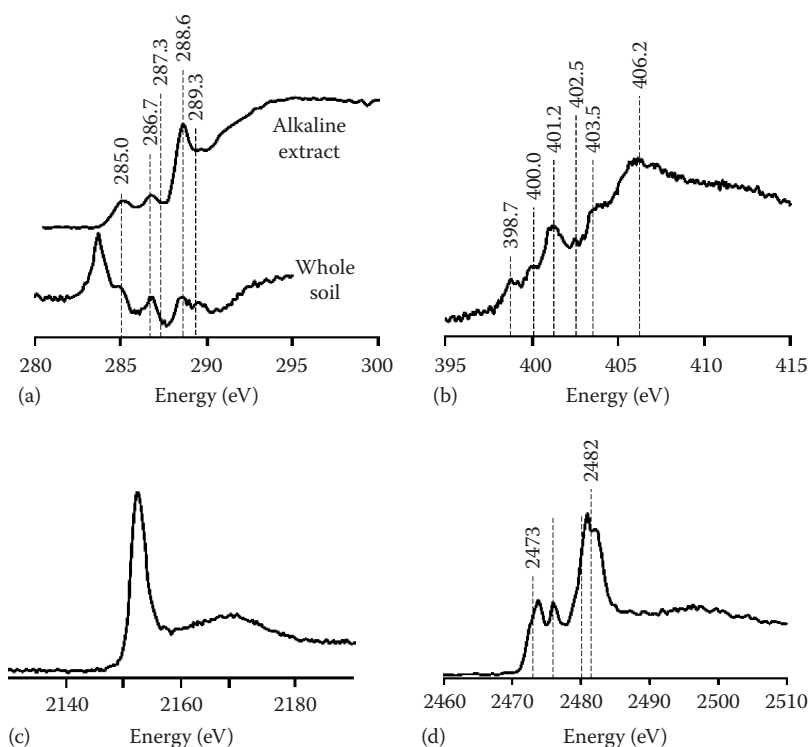
The ^{31}P nucleus is well suited to NMR due to its high natural abundance and relative NMR sensitivity. ^{31}P NMR analyses have been performed on solutions extracted from soils and on solid whole soils (see Toor et al., 2006). Solution-state ^{31}P NMR offers improved resolution and thus identification and quantification of P species; however, it suffers from the requirement to extract P-containing materials into solution and thus may not allow characterization of all P in a sample. Solid-state ^{31}P NMR can be


FIGURE 11.2 (a) Carbon K-edge XANES spectra acquired for the alkaline extractable organic carbon from a forest soil in western Kenya (Lehmann et al., 2008) and a whole soil from Elstow (Gillespie et al., 2009). (b) Nitrogen K-edge XANES spectrum acquired for a whole soil from Elstow (Gillespie et al., 2009). (c) Phosphorus K-edge XANES spectrum for topsoil from a German peat (Kruse and Leinweber, 2008). (d) Sulfur K-edge XANES spectrum acquired for whole soil taken from a podzol O horizon (Prietzel et al., 2007).

used to analyze a whole undisturbed sample without extraction; however, the association of soil P with Fe or Mn can render it invisible to ^{31}P NMR. Organic phosphates tend to remain unresolved and appear as a broad resonance between +1 and −1 ppm due to the wide variety of organic phosphate forms (e.g., phospholipids, nucleic acids, metabolic products) and their limited mobility. In solution-state ^{31}P NMR, rapid tumbling of extracted organic P-containing molecules leads to sharper signals. Toor et al. (2006) concluded that solution-state ^{31}P NMR is useful for characterizing the chemical composition of soil organic P, while solid-state ^{13}P NMR is more suited to the study of inorganic P components of soils.

11.2.2.2.2 Analytical Pyrolysis Mass Spectrometry

Analytical pyrolysis characterizes the chemical composition of products of controlled pyrolysis of a sample to obtain information pertaining to the nature of the organic matter present in the sample. The application of this technique to the analysis of organic matter in whole soils and soil extracts is given by Schnitzer and Schulten (1995). Several different approaches to using analytical pyrolysis exist including off-line pyrolysis, pyrolysis mass spectrometry, derivatization pyrolysis mass spectrometry, and Py-GC/MS. A detailed description of each technique is presented by Schulten and Leinweber (1996). In pyrolysis mass spectrometry, the mass/charge ratio (*m/z*) is used to differentiate

the pyrolysis products released during a rapid (Curie-point) or controlled heating of a sample. Several methods of ionization are available to promote the movement of pyrolysis products through the mass spectrometer: field ionization (FI), chemical ionization (CI), fast atom bombardment (FAB), and laser ionization (LI). Irrespective of the method of ionization used, distinctive patterns of pyrolysis products are produced (Figure 11.1b). After normalization of the *m/z* peak intensities, a qualitative assessment of the chemical nature of the organic C in a soil sample can be obtained. Incorporation of a gas chromatograph between the pyrolysis chamber and the mass spectrometer can further aid in the separation of similar pyrolysis fragments prior to detection and analysis by the mass spectrometer.

A cautionary note regarding the comparison of different *m/z* signal intensities is required. First, the intensities observed at any single *m/z* value may result from multiple pyrolysate fragments if they have the same *m/z* ratio. Second, the volatilization of different types of pyrolysis fragments varies (e.g., in pyrolysis FI MS, volatilization decreases with increasing polarity of the fragments). As a result, differences in signal intensities at various *m/z* values do not necessarily correlate with contents of the parent molecules present in the original soil samples. It is appropriate, however, to utilize variations in a given *m/z* signal intensity between samples run under a constant set of analytical conditions to infer compositional differences.

11.2.2.2.3 Fourier Transform Infrared Spectroscopy

FTIR can be used to determine the type of the atoms to which C is bound as well as the nature of the bond. Detailed identification of chemical structure is therefore possible. However, the application of FTIR to characterize the composition of SOM in whole soils is limited by two factors: the low organic matter content of most mineral soils and the presence of significant signals from soil mineral components. The use of "difference spectra" (spectrum of an untreated sample minus that of a pretreated sample) may provide more useful data. Subtraction of an FTIR spectrum obtained for a sample heated to 350°C to remove all organic matter from the FTIR spectrum obtained for the original soil can provide an indication of the nature of the organic components removed, provided no significant alteration to soil mineral components occurred during the heating process. Where significant alterations to soil mineralogy also occur on heating these changes will also be included in the difference spectrum. Figure 11.1c provides an example of a difference spectrum obtained for a soil.

11.2.2.2.4 X-Ray Absorption Spectroscopy

X-ray absorption spectroscopy (XAS) allows collection of atomic scale chemical information. A summary of the fundamentals of XAS techniques is given by Schulze and Bertsch (1995). In XAS, x-rays are absorbed by an atom at defined energies. In response, a higher-energy electron replaces the ejected electron, and excess energy is released in the form of fluorescence. The energy at which fluorescence occurs is characteristic for each electron within an atom and can be used to provide chemical information about a given type of atom (C, N, P, or S). XAS spectra are typically divided into two regions: the near-edge and extended region. X-ray absorption near-edge structure (XANES) spectroscopy examines the region before the absorption edge to around 100 eV past the edge. XANES spectra can also be referred to as near-edge x-ray absorption fine structure (NEXAFS) spectra. XANES spectra are sensitive to the oxidation state of the atom being examined. Resonances are identified by comparison with spectra acquired for standard compounds. In the extended region of x-ray absorption spectra, NEXAFS spectra provide information on coordination number, identity of nearest neighbors, and bond distances for the element being examined. XAS has been used to examine the chemical nature of organic C, N, P, and S found in soils (Figure 11.2).

Solomon et al. (2009) performed C K-edge XANES analysis of a suit of known organic C compounds indicative of those found in soil (carbohydrates, amino sugars, amino acids, phenols, quinine, benzenepolycarboxylic acid, and markers for black C). The acquired spectra showed distinct features and resonance positions for each form of carbon in the known compounds. Lehmann et al. (2008) provided the following broad classifications for XANES C resonances for alkaline extractable SOC: aromatic carbon ring structures (284–286 eV), phenolic/pyrimidine or imidazole carbon (286.4–287.4 eV), aliphatic carbon (287.3–287.8 eV), and carboxylic/amide carbon (288–289 eV). Working with whole soils (Figure 11.2a), Gillespie et al. (2009) identified

additional resonances and used XANES to quantify differences between bulk and rhizosphere soil. The C K-edge XANES spectra acquired by Gillespie et al. (2009) were complicated by the presence of residual C in the beamline and second-order O K-edge features that are typically absent from spectra acquired for pure organic compounds or samples with high (>50 mg C g^{-1} sample) carbon contents. XANES has also been combined with scanning transmission x-ray microscopy (STXM) to define spatial changes in carbon composition across microaggregates (Kinyangi et al., 2006; Lehmann et al., 2008) and black carbon particles (Lehmann et al., 2005; Liang et al., 2006, 2008). Solomon et al. (2009) concluded that C K-edge XANES may provide a means of fingerprinting complex organic C compounds of ecological importance; however, due to the broad spectral features found for organic carbon in soils (e.g., Lehmann et al., 2008), it is unlikely that XANES can be used on its own to provide an unambiguous chemical characterization of SOC.

Gillespie et al. (2009) performed N K-edge XANES on whole soils (Figure 11.2b) and attributed the following resonances to organic N structures: aromatic N in six-membered rings (398.7 eV), nitrilic and pyrazolic N (400.0 eV), amide (protein) N (401.2 eV), pyrrollic N (402.5 eV), nitroaromatic N (403.5 eV), and alkyl N (406.2 eV). Leinweber et al. (2007) presented a detailed systematic analysis of N K-edge XANES resonances obtained for a range of known organic N structures likely to occur in soils and concluded that N K-edge XANES can be used to reliably distinguish pyridinic and nitrile N (≤400 eV) from amide, nitro, and pyrrollic N (>400 eV). Jokic et al. (2004) used N K-edge XANES to detect the presence of heterocyclic N compounds in chemically unaltered whole soil samples.

Most applications of P XANES spectroscopy have focused on the K-edge; however, the speciation of P forms, particularly organic P, can be difficult or even impossible at the P K-edge. Kruse and Leinweber (2008) determined the nature of the P present in a series of inorganic and organic standard compounds as well as the topsoil (Figure 11.2c) and subsoil of a German peat using P K-edge XANES. The spectra obtained for the inorganic and organic standards showed only slight variations in the energy position of the main resonance and thereby offered little potential to distinguish inorganic from organic P. Additionally, little distinction was noted between the three organic P compounds (asolectin, ATP, and phytic acid). P XANES spectra collected at the L$_{2,3}$-edge instead of the K-edge contain more distinguishable features. Kruse et al. (2009) present a detailed analysis of the P L$_{2,3}$-edge XANES spectra obtained for a range of inorganic and organic forms of P. The P L$_{2,3}$-edge XANES spectra contained more spectral features than P K-edge spectra, particularly for the organic P compounds, leading Kruse et al. (2009) to suggest that quantitative differentiation of different types of P may be possible by applying linear combination fitting to P L$_{2,3}$-edge XANES spectra.

K-edge XANES can also be used to examine S speciation in soils (Prietzel et al., 2003; Solomon et al., 2005) (Figure 11.2d). S K-edge XANES resonances have been defined as 2472.6–2473.4 eV (reduced S in organic polysulfide, disulfide, monosulfide, and thiol structures), 2475.8–2481.3 eV (intermediate S

in sulfoxide, sulfone, and sulfonate structures), and 2482.5 eV (oxidized S in ester sulfate structures). Prietzel et al. (2007) used S K-edge XANES spectra to characterize the differences between S in whole soils with their corresponding humic extracts. In all soils examined by Prietzel et al. (2007), S was mainly present as organic mono- and disulfide (27%–52%), ester sulfate (14%–39%), and sulfone (15%–27%) with sulfoxide and sulfite having more minor contributes and an absence of sulfonate and inorganic sulfide. However, inorganic SO_4^{2-} cannot be differentiated from ester sulfate because both species have an equivalent oxidation state of +6. Prietzel et al. (2007) noted that the contribution of reduced forms of organic S (organic mono- and disulfides) increases and the contribution of ester sulfate and SO_4^{2-} decreases with increasing OC content and decreasing O_2 availability.

11.2.3 Physical Composition

The major input of organic carbon into soils results from the deposition of carbon captured by photosynthesis. Deposition within the soil matrix occurs in the form of root residues and the organic materials exuded during root growth. Shoot residues are first deposited onto the soil surface and enter the soil via leaching, in the case of dissolved organic materials (DOM), or through some form of mixing process that can be biotic (bioturbation), abiotic (opening of crack as swelling soils dry), or anthropogenic (cultivation). Approaches used to characterize the physical composition of SOM have been based on solubility, particle size, and density.

11.2.3.1 Dissolved Organic Materials

Dissolved organic materials represents a small proportion of the total organic material present in a soil. However, owing to its mobility and chemical properties, it can contribute significantly to soil processes through the provision of energy to microorganisms, complexation and transport of elements within the soil profile, and dissolution of soil minerals. DOM refers to the organic materials that do not settle out of the soil solution phase under the influence of gravity. It is operationally defined as the organic matter that passes through a 0.45 μm filter. At the upper limit of the DOM size, the distinction between DOM and particulate forms of SOM becomes ambiguous. DOM must be extracted from soils to allow quantitative and qualitative analysis. In the laboratory, DOM has been extracted in leachate collected at the base of undisturbed or disturbed soil columns or by suspension of soil in water or dilute salt solutions and collection of the <0.45 μm fraction (e.g., Dunnivant et al., 1992; Nelson et al., 1993). In the field, DOM can be collected using a variety of in situ devices, such as zero-tension or tension lysimeters using porous cups or plates (e.g., Weihermuller et al., 2007; Sanderman et al., 2008). It is important that the methods used to collect and isolate DOM are clearly specified and to assess the potential impacts that adsorption processes and filtering procedures could have on both the nature and amount of DOM isolated. Reviews pertaining to the collection, analysis, and fate of DOM in soils include Herbert and Bertsch (1995), Kalbitz et al. (2000), Neff and Asner (2001), and Kalbitz and Kaiser (2008).

DOM enters the soil as soluble material in water passing through vegetation, litter layers, or organic-rich soil surface horizons. It can also be generated in situ by adsorption/desorption reactions occurring on mineral surfaces, excretion of organic compounds from plant roots, excretion of metabolic waste products from soil organisms, and excretion and action of extracellular enzymes. DOM is lost through uptake and mineralization by soil organisms, sorption reactions with soil particles, precipitation reactions, and in leachate exiting the soil profile. The concentration of DOM in soil is governed by all these processes, and when expressed in terms of dissolved organic carbon (DOC), values typically range from 5 to 50 mg L^{-1} in surface and litter horizons, and from 0.5 to 5 mg L^{-1} or less in B and C horizons. When expressed on as annual fluxes, Michalzik et al. (2001) presented values of 10–40 g DOC m^{-2} $year^{-1}$ for surface organic horizons of temperate forest soils with an attenuation to 1–10 g DOC m^{-2} $year^{-1}$ through soil C horizons. Hope et al. (1994) suggested that DOC fluxes from terrestrial ecosystems should range from 1 to 10 g DOC m^{-2} $year^{-1}$ based on river DOC fluxes.

Reductions in DOC flux on passage through mineral soils are typically attributed to the processes of biologically mediated mineralization and adsorption to soil minerals. In a review of laboratory incubation studies, Kalbitz and Kaiser (2008) indicated that between 5% and 93% of the DOM present in soil solutions can be biologically mineralized. Kalbitz et al. (2003) concluded that the susceptibility to biological mineralization of DOM derived from forest floors, peats, and A horizons decreased with increasing degree of decomposition of the materials from which it was derived. Aromatic compounds potentially derived from lignin appeared to be the most biologically stable form of DOM (Kalbitz et al., 2003). Other important chemical characteristics of DOM that influence its reactivity, sorption behavior, and susceptibility to decomposition include its molecular size (10^2 to >10^5 g mol^{-1} [Homann and Grigal, 1992]), acidity (6–15 mol C kg^{-1} [Herbert and Bertsch, 1995]), and degree of hydrophobicity.

Differential adsorption of DOC onto soil minerals in two adjacent catchments with similar vegetation but different geological origins was proposed to account for the large differences in DOC concentration in catchment drainage water (Nelson et al., 1993). DOC sorption capacity was shown to vary significantly with soil depth, mineralogy, and organic C content (Guggenberger and Kaiser, 2003). Guggenberger and Kaiser (2003) found that surface-mineral horizons rich in organic carbon had little capacity to adsorb additional DOC (1–2 g DOC m^{-2}) compared to iron- and aluminum-rich B horizons (often >150 g DOC m^{-2}). Such measurements suggest that attenuation of DOC flux with increasing depth is most likely dominated by mineralization in the organic-rich surface horizons and then by adsorption reactions in iron- and/or aluminum-rich B horizons.

11.2.3.2 Particulate- and Mineral-Associated Organic Materials

Other than the organic matter that enters as individual molecules (DOM and root exudates), organic matter enters soil as particles that can vary significantly in size and chemical composition.

Particulate organic matter (POM) is composed of a variety of molecular components (e.g., cellulose, lignin, lipids, proteins) that have different availabilities to processes of decomposition. As POM is decomposed and mixed into the mineral soil, particle size is reduced and the potential for interacting with soil minerals and entering the mineral-associated organic matter fraction increases. A variety of names have been applied to the mineral-associated organic matter. In this work, we will use the abbreviation of mSOM to denote mineral-associated SOM. Interactions between minerals and decomposing SOM will result in SOM/mineral particle associations that increase in density as the extent of association increases. The density will be greatest for individual organic molecules adsorbed onto the surfaces of soil minerals (mSOM). Density will be lowest for large POM particles with only a small mass of mineral particles bound to their surfaces. As a result, methods for extracting, quantifying, and characterizing the POM in soils are based on selective collection of materials with different particle sizes, densities, or a combination of both (Christensen, 1996a, 2001).

A prerequisite to quantifying the allocation of SOM to different particle-size or density fractions is the use of disruptive techniques that separate the soil into primary particles or aggregations of particles. It is essential that any chemically or biologically induced alteration of the SOM or redistribution of SOM in response to soil structural degradation and exposure of mineral surfaces previously inaccessible mineral surfaces be minimized. Thus, the use of strong acids, alkalis, or chemical oxidation pre-treatments and the exposure of disrupted suspensions to high temperatures for prolonged periods should be avoided.

Early approaches to SOM fractionation used a strong initial ultrasonic disruption to disperse soil in an attempt to destroy all aggregation and obtain a suspension of primary particles after which particle-size and density fractionation procedures were initiated (e.g., Baldock et al., 1992). However, Golchin et al. (1994a) and Amelung and Zech (1999) showed that recovery of coarse POM decreased with increasing sonification time or energy resulting in a decrease in the physical size of POM and a redistribution of carbon into finer particle-size classes. Development of a two-step disruption process was demonstrated to minimize these problems (Amelung and Zech, 1999). Free POM not associated with mineral materials was removed subsequent to an initial minimal disruption process in which the integrity of soil aggregates was maintained. A more vigorous second step achieving complete aggregate disruption and dispersion was then applied to release pieces of SOM that were occluded within soil aggregates and allow the separation of this material from mSOM. In its simplest form, this approach results in the isolation of three SOM fractions:

- fPOM—free pieces of organic residue found between soil particles
- oPOM—occluded pieces of organic residue found within aggregations of soil particles
- mSOM—organic matter strongly bound to mineral particle surfaces

Additional approaches to disrupt soils and perform particle-size and density fractionations have used a combination of sodium saturation and physical dispersion methods (e.g., Skjemstad et al., 2004) or have applied a more complex combination of particle-size and density fractionation steps with increasing amounts of disruption and/or increasing density fractionation steps. These latter approaches have been designed to progressively isolate SOM materials from free through occluded to various fractions associated to different extents with mineral components (e.g., Six et al., 2001; John et al., 2005; Sohi et al., 2005; Swanston et al., 2005).

Once isolated from bulk soil, a variety of methodologies can be applied to particle-size and density fractions to quantify rates of turnover and chemical composition. Acquiring $\Delta^{14}C$ measurements for the organic carbon found in 2000-63, 63-2, and <2 μm fractions of soils allowed Trumbore and Zheng (1996) to estimate turnover rates. After normalization of the $\Delta^{14}C$ values to those measured for the 2000-63 μm fraction, both depletions and enrichment of ^{14}C were found with decreases in particle size, indicating a respective increase or decrease in age of the carbon with decreasing particle size. Schöning et al. (2005) measured the percentage of modern carbon in the Ah horizons of luvisols, leptosols, and phaeozems under a European beech (*Fagus sylvatica* L.) forest and found a consistent trend of decreasing amounts of modern SOC with decreasing particle size.

The extent of decomposition and turnover times of organic carbon found in fine (<0.2 μm) and coarse (0.2–2.0 μm) mSOM fractions was assessed by Kahle et al. (2003) using $\delta^{13}C$ and $\Delta^{14}C$ measurements. Organic carbon found in the fine-clay fraction was more enriched with ^{13}C and ^{14}C, suggesting a greater extent of microbial processing but a shorter turnover time than coarse-clay organic carbon. Enrichments in ^{13}C and a decrease in C/N ratio with decreasing particle size were also observed by Amelung et al. (1999). The general lack of consistency with respect to changes in ^{13}C and ^{14}C enrichment with decreasing particle size suggests that different processes of SOC stabilization operate in different soils and that relatively young and potentially labile SOC may be stabilized against mineralization, particularly through the formation of mSOM via interactions with mineral surfaces.

The application of density fractionation, either independently or combined with particle-size fractionation methods, has also been used to isolate and characterize SOC fractions with different liabilities. Trumbore and Zheng (1996) found that SOC in dense soil fractions (>2.0 g cm⁻³) was more depleted in ^{14}C than that found in less-dense fractions (<2.0 g cm⁻³). John et al. (2005) determined the $\delta^{13}C$ of the following four density fractions isolated from a silty soil that had undergone a C3/C4 plant species transition:

- Free-POM <1.6 g cm⁻³ ($fPOM_{<1.6}$)
- Light-occluded POM <1.6 g cm⁻³ ($oPOM_{<1.6}$)
- Dense-occluded POM 1.6–2.0 g cm⁻³ ($mSOM_{1.6-2.0}$)
- Mineral-associated SOM >2 g cm⁻³ ($mSOM_{>2.0}$)

The $\delta^{13}C$ data were used to calculate a mean age of the C in each pool. Elemental analyses showed a decreasing trend in C:N ratio in progressing from the $fSOM_{<1.6}$ through to the $mSOM_{>2.0}$ fractions

that were suggested to indicate an increase in the degree of degradation and humification. The mean age of SOC in these fractions and the values obtained for percent modern carbon (Rethemeyer et al., 2005) did not follow the same trend, suggesting that the oldest carbon in a soil may not be the most decomposed. Such a situation can only arise when organic materials having a chemical composition that renders them biologically labile are stabilized against biological attack within the soil matrix.

A simpler density fractionation scheme using a density solution of 1.7 g cm^{-3} was used by Swanston et al. (2005) to isolate three fractions (fSOM$_{<1.7}$, oSOM$_{<1.7}$, and mSOM$_{>1.7}$) from ^{14}C-labeled and unlabeled forest soils. The fSOM$_{<1.7}$ was found to be the most active fraction based on the measurement of SOC content, C/N ratio, and Δ^{14}C. The oSOM$_{<1.7}$ fraction appeared to be less dynamic with a minimal entry of ^{14}C since the labeling event. Based on ^{13}C NMR analyses (Golchin et al., 1994a; Sohi et al., 2001, 2005; Poirier et al., 2005), oPOM is more degraded compared to fPOM; however, this is not consistent with the higher C/N ratios measured by Swanston et al. (2005). Such high C/N ratios would be consistent with the presence of a significant amount of charcoal C, which could mask the entry of new labeled ^{14}C into this pool based on Δ^{14}C measurements alone. ^{13}C NMR analyses of oPOM fractions shown in Figure 11.3 (Sohi et al., 2001; Poirier et al., 2005) do indeed suggest the presence of charcoal-like carbon given the significant resonances in the vicinity of 130 mg kg^{-1}. A significant movement of new labeled ^{14}C into the dense mineral-associated SOC fraction was also measured by Swanston et al. (2005). The depleted ^{14}C signature of this dense fraction at the near-background control site suggested that at the ^{14}C-labeled site, the dense fraction consisted of at least two different pools of SOM: a fast-cycling pool and an older more stable pool. The presence of a labile pool of carbon within the dense mineral-associated SOM fraction was

supported by the lack of a difference in rate of carbon respiration from free particulate and dense mineral-associated SOM over the first 120 days of an incubation study (Swanston et al., 2002).

Although it is challenging to apply all the methods of analysis described to a soil sample (i.e., elemental contents and ratios, isotopic measurements for establishing turnover rates, and NMR to define chemical composition), doing so allows a more complete picture of the nature and dynamics of SOM fractions.

11.2.4 Biological Composition

Research aimed at examining SOM in a biological context have attempted to differentiate organic matter on the basis of its susceptibility to decomposition and mineralization. Schemes developed to quantify the amount of biologically labile carbon have taken two general approaches: (1) quantification of the amount of carbon or nitrogen associated with the living soil microbial biomass or (2) quantification of a product of a biological process (e.g., CO_2–C mineralized over a defined time interval).

Measurements of soil microbial biomass are assumed to be representative of the total mass of living microorganisms present in a soil. The importance of microorganisms to soil functioning is well recognized (Dalal, 1998; Stockdale and Brookes, 2006). The soil microbial biomass regulates most transformations of SOM, responds rapidly to variations in climate or management, and has been defined as the eye of the needle through which all soil carbon passes (Jenkinson, 1977; Smith and Paul, 1990). Soil microbial biomass is routinely measured using a variety of direct and indirect techniques based on either carbon or nitrogen dynamics. Direct techniques attempt to quantify the amount of carbon released to the soil after a fumigation event designed to lyse living microbial cells. The carbon released is measured by an extraction or incubation technique (Jenkinson, 1976;
FIGURE 11.3 Solid-state ^{13}C NMR spectra obtained for fPOM, oPOM, and mSOM collected by Sohi et al. (2001) and Poirier et al. (2005) showing strong unsaturated carbon resonances, particularly in the oPOM fraction, consistent with the presence of charcoal and other forms of thermally altered organic matter.

Vance et al., 1987a, 1987b). Indirect techniques involve quantification of the respiration response on addition of a degradable substrate (Anderson and Domsch, 1978). Although the preceding comments have focused on the use of carbon to quantify soil microbial biomass, equivalent approaches exist based on the measurements of nitrogen (Brookes et al., 1985), sulfur (Saggar et al., 1981), and phosphorus (Brookes et al., 1982).

Once the measurements of extracted or mineralized carbon, nitrogen, phosphorus, or sulfur are obtained, conversion factors are applied to account for a lack of complete cell lysis and nonquantitative detection. For example, conversion factors of 0.45, 0.45, and 0.40 have been suggested to convert measurements of extracted carbon, nitrogen, and phosphorus, respectively, into their equivalent values within soil microbial biomass (Brookes et al., 1982, 1984, 1985; Jenkinson et al., 2004). Although these conversion factors have been shown to be adequate for microorganisms in cultures, they may vary across the diverse community of microorganisms found in soils and between different soils. Furthermore, the calculation of the size of the microbial biomass from CO_2 production requires a reliable estimate of the proportion of C that is assimilated and retained by the cell, that is, the microbial efficiency. This microbial efficiency, is not easily quantified, differs for different species within the soil microbial community (Anderson and Domsch, 1973) and varies on the basis of soil properties (Schimel, 1988) and the quality of the decomposing residue (Hart et al., 1994).

Carbon associated with the soil microbial biomass can account for 0.3%–7% of the total SOC (Wardle, 1992). Due to its short turnover time of <1 year (Jenkinson and Rayner, 1977; Jenkinson and Ladd, 1981; Ladd et al., 1981; Jenkinson and Parry, 1989; Wardle, 1992), the carbon associated with soil microbial biomass is considered to be a component of the active or labile pool of SOM. Measurements of soil microbial biomass are considered to provide a sensitive indicator of potential direction and relative magnitude of management-induced changes in SOM (Powlson and Jenkinson, 1976). However, the high spatial and temporal variability in the measurements of the soil microbial biomass and its dependence on soil water content, temperature, and substrate availability in the field will limit the usefulness of single point in time measures as a robust indictor of changes in SOC status. This was shown in an assessment of several Australian field trials, which indicated that very high numbers of field replicates (up to 93) were needed to significantly detect a 20% difference in soil microbial biomass carbon from control treatments (Broos et al., 2007).

There is no doubt that measures of soil microbial biomass provide an assessment of the potential rate of soil biological processes. However, such measures may or may not be related to actual biological process rates. Strong relationships will not exist where only a certain component of the entire microbial community involved in the process being quantified or where all individuals capable of contributing are doing so at different rates.

Quantification of process rates provides an alternative to define the functional capability a soil microbial population. An example of quantifying a process rate is the measurement of the amount of organic carbon mineralized to carbon dioxide over a given time period. Haynes (2005) has reviewed the use of potentially mineralizable carbon and nitrogen to assess the biological lability of SOM. In this approach, the amount of organic carbon or nutrient (typically nitrogen) that can be converted into an inorganic from over a defined time interval is quantified (e.g., Campbell et al., 1991; Franzluebbers et al., 1994). It is important to note that the mineralization of carbon and nitrogen are not analogous. Mineralization of organic carbon results in a gaseous product that, for the most part, cannot be used by soil microorganisms and can be quantitatively recovered in an adequate experimental apparatus. Alternatively, organic nitrogen that has been mineralized to ammonium can be reused (immobilized) by soil organisms, volatilized as ammonia under certain soil pH conditions, nitrified to nitrate, and subsequently denitrified or leached if open incubation systems are used. Estimates of gross nitrogen mineralization are required to obtain data analogous to carbon mineralization (Bengtsson et al., 2003; Murphy et al., 2003; Flavel and Murphy, 2006).

Mineralization of carbon and nutrients results from a complex set of biochemical processes conducted by a wide range of organisms and thus provides a measure of soil functional capacity. Organic C mineralization is often called "soil respiration," "basal respiration," or "microbial respiration." The amount or rate of C mineralization measured over periods from a few days to a few weeks is commonly used as an indicator of biological activity, whereas the total amount of CO_2–C released on a longer time frame (>3 months) is considered to provide information about the fraction of SOC that is readily available to decomposer organisms. Mineralized C can be expressed either per unit mass of soil (mg CO_2–C g^{-1} soil) or as a proportion of the original SOC present (mg CO_2–C g^{-1} SOC). When expressed per unit mass of soil, information regarding the size of the mineralizable C fraction is obtained; whereas, when expressed per unit mass of SOC, an indication of the degradability of the organic carbon present in a soil is obtained.

Although measurements of mineralizable nitrogen require careful interpretation, the measure of net nitrogen mineralization (change in inorganic nitrogen status through time) can provide a measure of the contribution that decomposition processes can make to the supply of plant-available N. Mineralizable soil organic N (SON) is composed of various organic substrates, including microbial biomass, residues of recent crops (mainly POM), and humus (HUM). The mineralizable SON can be measured as potentially mineralizable N using an aerobic incubation under optimum moisture and temperature conditions (Franzluebbers et al., 1994; Chan et al., 2002) or under field conditions (Dalal et al., 2005) using the method developed by Raison et al. (1987). Attempts to correlate mineralizable SON with measures of total SON or SOC have not been very successful. It is suspected that one of the major reasons for this lack of success is related to differences in the allocation of SON and SOC to different forms of SOM, the variability of C:N ratio of these materials and the impact this would have on the mineralization/immobilization balance.

11.2.5 Defining Biologically Relevant Soil Organic Matter Fractions

Variability in elemental, chemical, physical, and biological composition provides the different components of SOM with an ability to contribute to a range of soil properties and processes (see Section 11.4). This variability also leads to differences in rates of turnover as demonstrated using ¹⁴C measurements (e.g., Ladd et al., 1981; Anderson and Paul, 1984; Swanston et al., 2005). In the context of SOM turnover studies, one objective of fractionating SOM is to quantify the allocation of SOM to materials that are differentially available to decomposition. In this section, a conceptual model of SOM decomposition will be presented and used to identify biologically relevant SOM fractions that can be quantified through measurement.

Prior to the presentation of the model, decomposition and its component processes will be defined to ensure no ambiguity exists pertaining to the processes being referred to. Decomposition is used to define the alteration of the original form of an organic material. Mineralization is used to define the conversion of an organic form of an element into an inorganic from (e.g., organic carbon to CO_2 or organic N to NH_3). Mineralization of carbon and nutrients is thought to dominantly occur within cells in response to respiration and other metabolic processes. The extent to which mineralization, particularly nutrient mineralization, can occur external to cells remains unquantified. However, if mineralization external to the cell is a dominant process, then the concept of ecological stoichiometry would be flawed and constraining carbon and nutrient cycling simulation models with carbon to nutrient ratios would be unsuccessful. Assimilation is defined as the use of carbon and

other elements in an organic material to create new biochemicals required for maintenance and growth of the decomposer community. As some of the assimilated carbon and nutrients may be excreted in an organic form as metabolic waste products, net assimilation should be used to refer to the amount of carbon and nutrients taken up and retained within the decomposer community. Additionally, since organic materials in soils are acted on by extracellular enzymes, it is possible that substrate alteration can occur without subsequent assimilation or mineralization. Possible examples of this include the adsorption of products of extracellular enzyme activity on soil mineral surfaces or the leaching of these products through the soil profile before they can be used. In both instances, the original organic material is altered but not accompanied by either a mineralization or assimilation. In the context of these definitions, decomposition is taken to represent the total of the individual processes of mineralization, assimilation, and alteration.

In the decomposition model (Figure 11.4), all processes occur in the aqueous phase of the soil and the behavior of simple and complex substrates is differentiated. Simple substrates are defined as soluble molecules that can cross cell membranes without further alteration. Once inside a cell, simple substrates can be mineralized, assimilated, or transformed into products of metabolic activity that are excreted back into the soil solution. Excreted metabolic products may be further transformed in the soil solution and/or reused by individuals within the decomposer community. Complex substrates consist of polymeric or multicomponent mixtures that are not soluble and cannot pass through a cell membrane in their original state.

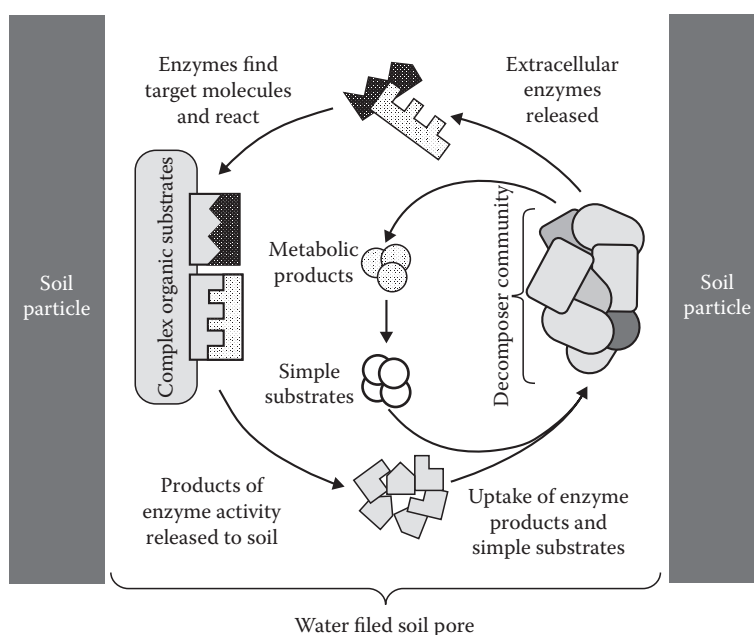
Additional processes are required for decomposer organisms to use complex substrates including excretion of extracellular


FIGURE 11.4 Schematic model of the decomposition of organic materials in soil. Substrates may exist as simple soluble molecules or in particulate form requiring enzymes to liberate molecules capable of passing cell membranes. Products of metabolic activity may or may not serve as subsequent sources of either energy or nutrients.

enzymes, diffusion of the enzymes to their target sites, release of the products of enzyme activity, diffusion of the products back to the decomposers, and uptake of the products. For both simple and complex substrates, diffusion of soluble materials is required, and thus, the relative position of the substrate and the organism is important. Minimizing the path lengths of diffusion of both enzymes and products will enhance the rates of substrate decomposition and assimilation. Although each of the various organic components identified in Figure 11.4 (extracellular enzymes, products of enzyme activity, simple substrates, and metabolic products) is grouped together in the figure, this is only to illustrate the components involved in the process of decomposition. In reality, all these components will diffuse throughout the soil solution.

Baldock (2007) indicated that two types of controls operate to determine the biological stability of organic materials in soils (Figure 11.5). Biological capability controls whether or not a particular form of organic matter can decompose, while biological capacity controls the rate at which decomposition will proceed. Controls over the biological capability were suggested to include three factors: chemical recalcitrance, decomposer capability, and protection by the soil matrix. Chemical recalcitrance describes the type and arrangement of atoms and bonds within an organic substrate. Some organic material in soil offers little chemical recalcitrance to decomposition (e.g., cellulose and proteins) while others contain components that are highly resistant at least on a timescale of decades (e.g., charcoal). Decomposer capability refers to the presence of the appropriate DNA sequences required to construct the enzymes needed to attack and decompose the molecular components within the organic materials present. The third factor is protection by the soil matrix, which describes whether a molecule is in a position in the soil where it is accessible to enzymes. Biological capacity

FIGURE 11.5 Factors important to defining the biological stability of organic materials in soil. Factors describing biological capability define whether a particular form of SOM can be decomposed or not. Factors describing biological capacity define the rate at which decomposition occurs rather than whether it will or will not occur. Rate modifiers include properties such as temperature and water content, which need to be combined with the duration of exposure to favorable conditions to define the biological capacity. (Modified from Baldock, J.A. 2007. Composition and cycling of organic carbon in soil, p. 1–35. *In* P. Marschner and Z. Rengel (eds.) Soil biology. Vol. 10. Nutrient cycling in terrestrial ecosystems. Springer-Verlag, Berlin, Germany.)

refers to processes that affect the rate of decomposition but not whether a given molecule is decomposable. Biological capacity is defined by a series of factors governing the rate of biological processes (e.g., soil temperature and water content) and the duration of exposure to favorable conditions.

Combining the model of decomposition processes (Figure 11.4) with the concepts of biological stability (Figure 11.5) provides a means to identify biologically relevant fractions of SOM that decompose at different rates. DOM contains a variety of molecular structures with different chemical recalcitrance that are free to diffuse throughout the soil solution. Given the requirement for all substrates to pass through an aqueous phase prior to uptake and utilization by the soil decomposer community, DOM is likely to be the best indicator of the instantaneous availability of organic material at any given point in time. However, quantitative estimates of DOM content are unlikely to provide a good indication of the longer-term biological availability of SOM.

One of the most important forms of SOM, from the point of view of provision of a longer-term supply of energy to soil organisms, is the POM fraction with its high content of more easily degradable material (e.g., cellulose). POM may or may not provide nutrients depending on its elemental ratios. POM with high C:nutrient ratios (e.g., C/N ratio >40) will tend to immobilize nutrients as its carbon is mineralized. This may reduce the availability of nutrients to plants, but also enhance nutrient retention within surface soil layers by limiting losses due to leaching. The mSOM fraction tends to have a chemical composition more indicative of decomposed materials [lower C:nutrient ratios and higher ratio of alkyl:*O*-alkyl carbon (Baldock et al., 1997a)]. When considered in conjunction with its high level of interaction with mineral surfaces, the mSOM fraction is more resistant to decomposition than the POM fraction. The low C:nutrient ratios of mSOM suggest that it can contribute significantly to the provision of nutrients to plants and decomposer organisms. An additional fraction of SOM that is important to consider and monitor is charcoal or black carbon. This material has been found to account for up to 60% of the carbon in a soil (Skjemstad et al., 1996, 1998, 1999, 2002; Schmidt et al., 1999; Skjemstad and Taylor, 1999). Although a fraction of newly created charcoal may be decomposable (Hamer et al., 2004; Marschner et al., 2008), a high recalcitrance of charcoal C to biological mineralization in laboratory-based incubation has also been demonstrated (Baldock and Smernik, 2002). Long-residence times measured for charcoal in soil also suggest that a significant proportion is resistant to decomposition (Pressenda et al., 1996; Skjemstad et al., 1998; Swift, 2001; Krull et al., 2003, 2006).

Given the more recalcitrant behavior of charcoal carbon than the other forms of soil carbon, it is important to be able to selectively quantify the amount of charcoal carbon. In Figure 11.6, the impact that the presence of increasing proportions of charcoal carbon can have on SOC dynamics is shown using a modeling exercise completed with a modified RothC soil carbon model. In this modified model, the original resistant plant material (RPM)

	Proportion of SOC allocated to charcoal			
	0.00	0.10	0.25	0.50
Total organic carbon	55.3	62.6	73.5	91.6
Non-charcoal organic carbon	55.3	49.8	41.5	27.7

FIGURE 11.6   Changes in total organic carbon (TOC), 2.0–0.053 mm POC, carbon associated with the <0.053 mm fraction (HUM), and charcoal carbon (Char-C) estimated from the RothC soil carbon model with different initial contents of charcoal carbon. For this modeling exercise, the total organic carbon at the start of the simulation was kept constant, the fraction of noncharcoal carbon allocated to the POC and HUM fractions was kept constant, and carbon inputs over the simulation period were set to zero. The DPM and two biomass pools in the RothC model were included in the modeling exercise but are omitted from the figure. The 1970–2005 average climate data for Beverly, WA, Australia were used. The table at the bottom of the figure gives the final values obtained after 50 years of simulation for total organic carbon and the noncharcoal organic carbon (POC + HUM) in units of Mg C ha^{-1} for the 0–30 cm soil layer.

and HUM fractions are equated to the POM and mSOM fractions described above. For all four modeling scenarios, the same starting level of SOC was used (127 Mg C ha^{-1}), and the allocation of carbon to each of the noncharcoal fractions was fixed at a given percentage of the total noncharcoal C components (27% for POC and 69% for mSOM). Over the 50-year period, inputs of carbon were set to 0. With increasing initial allocation of SOC to the charcoal fraction, the decline in TOC over the simulation period was reduced. However, when the dynamics of the POC and mSOM fractions are examined, despite there being more total carbon where charcoal accounted for 50% of the initial SOC, the amount of noncharcoal C remaining after 50 years was largest in the soil with no charcoal. If soil productivity was related more to the amount of mSOM carbon than charcoal carbon present, despite the greater loss of carbon from the soil with no charcoal, a higher level of productivity would be retained in this soil due to the higher amounts of mSOM maintained.

As a result of the preceding discussion, selective quantification of biologically relevant fractions of SOM requires an allocation of SOM across POM, mSOM, and charcoal fractions for longer-term studies (weeks to years) and an additional inclusion of DOM for short-term studies (hours to days). Although many approaches varying in number of fractions isolated and complexity of the fractionation process exist, it is suggested that the most simple fractionation system capable of allocating SOM to the POM, mSOM, charcoal fractions, and possibly DOM, depending on the application, would be most practical for the

potential broadscale application of quantifying the implications of land use and land-use change on SOM cycling. Baldock and Skjemstad (1999) proposed a three-component fractionation scheme to identify measurable SOM fractions for soil samples sieved to <2 mm: POC (organic carbon associated with 2000-53 μm particles), HUM (organic carbon associated with <53 μm particles), and ROC (resistant organic carbon associated with <53 μm particles after removal of nonresistant materials with UV photo-oxidation and correction with ^{13}C NMR analyses). Recently, modifications have been made to the Baldock and Skjemstad (1999) fractionation scheme to cover all forms of SOM at a given location and to account for recent analyses that have indicated the presence of significant quantities of charcoal in the POM fraction (Figure 11.7).

11.2.6 Consistency between Biologically Relevant Soil Organic Matter Fractions and Pools of Carbon in Simulation Models

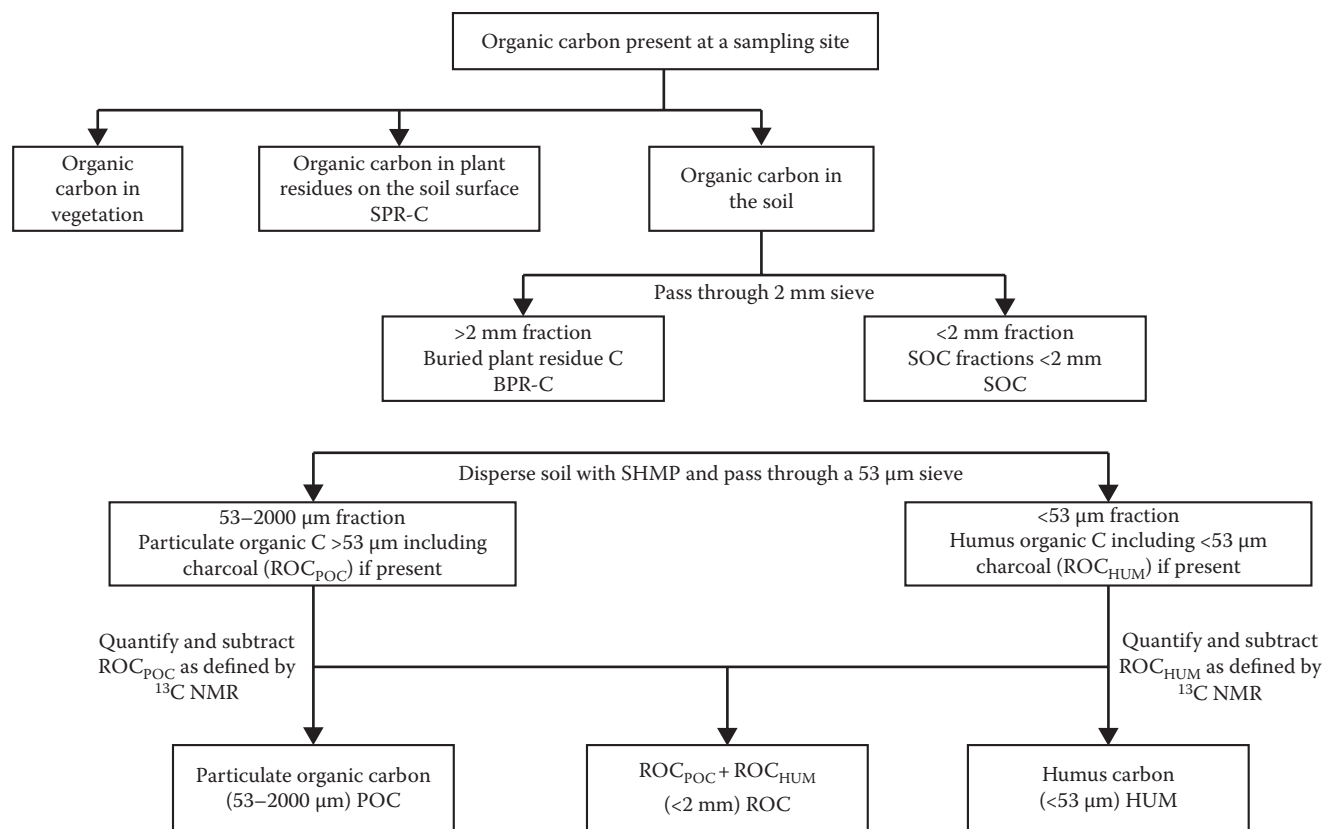
Simulation models of SOC cycling (e.g., Rothamsted [Jenkinson et al., 1987], Century [Parton et al., 1987], and APSIM [McCown et al., 1996]) are often based on conceptual pools of carbon that are not measured directly. The construct of most SOC models is similar and includes fractions of SOC with a rapid turnover (annual), moderate turnover (decadal), and slow turnover (millennial) as well as a passive or inert component. It has been


FIGURE 11.7 Schematic presentation of the proposed methodology for defining the allocation of total SOC to its ecologically significant component fractions. SPR-C is the organic carbon associated with plant residues on the soil surface collected on an area basis. BPR-C is the organic carbon in buried plant residues having a size >2 mm. SOC is the total amount of organic carbon found in the <2 mm fraction of the soil. POC is the organic carbon found in the noncharcoal component of particles 53–2000 μm in size. HUM is the organic carbon found in the noncharcoal component of particles <53 μm. ROC is the resistant organic carbon obtained by adding together the charcoal C found in particles <2 mm (the sum of charcoal C found in the 53–2000 μm and the <53 μm fractions). SHMP is sodium hexametaphosphate.

recognized that developing a capability to replace these conceptual pools of SOC with measurable pools would offer several advantages: (1) internal verification of appropriate allocations of SOC to pools, (2) greater mechanistic understanding of the implication of management and environment on the components of SOC most affected, and (3) improved confidence in simulation outcomes. A suitable fractionation procedure should be capable of isolating and quantifying the allocation of SOC to pools that differ significantly in their biological availability (Baldock, 2007).

Several methods have been proposed to link measurable fractions of SOC to the conceptual pools contained within models using density fractionation techniques (Christensen, 1996b; Poirier et al., 2005; Sohi et al., 2005). However, the biological availability of the carbon in each fraction of these studies was never measured, and no attempt was made to substitute the measurable pools of SOC into a working carbon simulation model to demonstrate the utility of this proposal. Skjemstad et al. (2004) showed that the pool structure of the RothC model could be approximated using a three-component fractionation scheme as described by Baldock and Skjemstad (1999). Skjemstad et al. (2004) demonstrated that the POC, HUM, and ROC fractions

could be used to replace the RPM, HUM, and inert organic matter (IOM) pools of the RothC model, respectively. This was an important step forward in simulating SOC dynamics and demonstrated the potential for "modeling the measurable" (Christensen, 1996b; Magid et al., 1996; Baldock, 2007).

It must be noted that the soil microbial biomass (BIOf and BIOs in the RothC model) and decomposable plant materials (DPM in the RothC model) were not included in the fractionation scheme described by Baldock and Skjemstad (1999) or used in the RothC calibration by Skjemstad et al. (2004). The main reasons for this were as follows:

1. Difficulties associated with quantitatively separating the microbial biomass from the other forms of SOC
2. The questionable link between measures of microbial biomass carbon and rates of mineralization of SOC
3. The contributions made by the DPM, BIOf, and BIOs fractions to the total SOC are small and within the errors associated with measurement of the other larger fractions
4. These fractions equilibrate quickly in SOC simulation models

11.3 Quantifying Soil Organic Matter Content and Allocation to Fractions

Soil organic matter content, as indicated in Section 11.2, is typically quantified by measuring the content of organic carbon. Initially, measurements of SOM or SOC were completed to investigate pedogenic processes and, given its diverse and important functions in soils (Section 11.1), to provide a measure of soil productivity. However, being able to accurately define the content of organic carbon in soil has become important because of the potential for soils to sequester atmospheric CO_2–C (Section 11.1). An additional requirement to move beyond the measurements of total organic carbon content and define the allocation of organic carbon to its ecologically significant fractions has emerged to support and improve predictions related to the influence of land use and management on soil carbon dynamics.

11.3.1 Direct Measurement of Soil Organic Content and Component Fractions

Methods to measure the content of SOC have been assembled recently by Skjemstad and Baldock (2008) and previously by Nelson and Sommers (1996) and include dry and wet combustion methods. Total C analyses involve the complete conversion of all C (organic and inorganic) in a soil to CO_2 and quantification of the evolved CO_2 by various means (e.g., infrared detection, increased mass of an ascarite trap, or others). Corrections for the presence of inorganic C must be performed when using total C methods to quantify SOC contents. Of the methodologies currently available, a dry combustion-automated analyzer that measures CO_2 evolution with an infrared detector is the preferred methodology for determining SOC, provided accurate estimates of inorganic C contents can be obtained where required or samples can be pretreated to remove all inorganic C (Baldock and Skjemstad, 1999).

The successful calibration of the RothC model using measurable fractions of SOC has led to the development of the protocol described in Figure 11.7. This methodology differs slightly from that presented by Baldock and Skjemstad (1999) in that the resistant fraction (charcoal) is quantified in both the 2000-53 µm particulate and <53 µm HUM fractions rather than just the HUM fraction. Once isolated and dried, the carbon content of the various fractions (SPR-C, BPR-C, SOC, 53–2000, and <53 µm) is quantified using the dry combustion technique. The amounts of carbon associated with the POC, ROC, and HUM fractions are then defined after using ${}^{13}C$ NMR to quantify the allocation of carbon to the ROC fractions in the 53–2000 and <53 µm materials (ROC$_{POC}$ and ROC$_{HUM}$, respectively).

11.3.2 Proximate Analyses

The SOM fractionation process described in Section 11.1 is time-consuming to complete (3–6 weeks to progress a sample from start to finish depending on the contents of carbon present in the soil and its fractions), requires the use of expensive analytical instrumentation (e.g., a ${}^{13}C$ NMR spectrometer and a UV photo-oxidizer system), and involves the use of hazardous chemicals (e.g., HF). It would therefore be unlikely that this SOM fractionation process would move beyond a research implementation and become a routine measure available to land managers interested in understanding the impact of management practices. Provision of a more cost-effective and rapid means of quantifying SOC content and its allocation to component fractions is required. The development of such a capability would also be very useful to support the carbon cycling work and scenario predictions by providing appropriate data for initializing soil carbon models.

Diffuse reflectance mid-infrared spectroscopy (MIR) offers a simple, rapid, and low-cost methodology that is sensitive to both mineral and organic materials present in soils. In MIR, the chemical bonds associated with a variety of organic functional groups (alkyl, carbohydrate, carboxyl, amide, amine, aryl) can be identified (Janik et al., 2007). The problem is that signals from these components are often hidden within soil MIR spectra by signals derived from soil mineral components. The development of partial least squares (PLS) regression approaches and their application to spectroscopic data has allowed the signals obtained throughout the entire MIR spectrum to be examined for correlation to a set of analytical values derived from traditional laboratory procedures. The ability of MIR/PLS to predict total organic carbon was demonstrated by Janik and Skjemstad (1995) and Janik et al. (1998). Using the PLS process detailed by Haaland and Thomas (1988), Janik et al. (2007) applied the MIR/PLS approach to the data collected for total organic carbon content and its allocation to the POC and ROC (charcoal C) fractions. Successful calibration was achieved and used to compare laboratory-derived analytical data with corresponding data derived from the MIR/PLS predictions (Figure 11.8). The predictive capability for total organic carbon was excellent and that for ROC (charcoal C) was good. Agreement between predicted and measured values for POC was not as good but remained acceptable. Given the stronger dependence of POC on the nature of the vegetation from which it was derived, it is perhaps not surprising that predictability of this fraction was lower. With time and the development of additional calibration data, it may be possible to define more specific calibrations for POC derived from soils under different vegetation types. The current approach defined by Janik et al. (2007) calculates the allocation of carbon to the HUM fraction by difference (HUM = total – particulate – resistant).

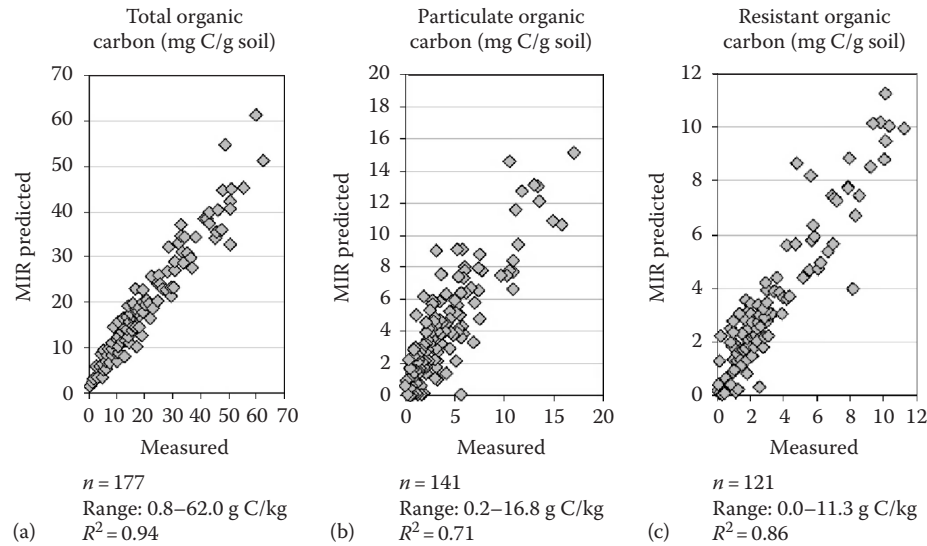
It should be recognized that the MIR/PLS process is completely empirical and may be based as much on positive correlation with MIR signals from organic materials as positive or negative signals derived from particular soil minerals. Subsequent unpublished MIR/PLS work completed in the same laboratory has indicated that although the calibrations presented by Janik et al. (2007) provided adequate estimates of soil carbon fractions, improved predictions could be obtained by performing sample set–specific calibrations. To perform these sample set–specific


FIGURE 11.8 Relationship between measured and MIR/PLS predicted contents of (a) total organic carbon, (b) POC (53–2000 μm), and (c) ROC (dominated by charcoal). (Adapted from Janik, L.J., J.O. Skjemstad, K.D. Shepherd, and L.R. Spouncer. 2007. The prediction of soil carbon fractions using mid-infrared-partial least square analysis. Aust. J. Soil Res. 45:73–81.)

calibrations, a subset of 10%–20% of the samples were selected to span the range of predicted values, analyzed using the laboratory procedure and used to recalibrate the MIR/PLS estimation procedure.

The MIR/PLS procedure appears to offer a robust, rapid, and cost-effective way to predict the total amount of organic carbon in soils as well as its allocation to fractions. With further testing and development of calibration data sets, this methodology may be able to underpin soil carbon modeling activities and provide useful data to land managers.

11.4 Functions of Organic Matter in Soil

Despite its often minor contribution to the total mass of mineral soils, SOM can influence a variety of soil properties, ecosystem functioning, and the magnitude of various obligatory ecosystem processes (Table 11.3). The properties influenced by SOM have been classified into three groups: biological, chemical, and physical. It should be noted that strong interactions and interdependencies exist between these groups. For example, the ability of SOM to chelate multivalent cations can affect its potential to

TABLE 11.3 Properties and Functions of Organic Matter in Soil

Property	Function
Biological properties	
Reservoir of metabolic energy	Organic matter provides the metabolic energy, which drives soil biological processes
Source of macronutrients	The mineralization of SOM can significantly influence (positively or negatively) the size of the plant-available macronutrient (N, P, and S) pools
Ecosystem resilience	The buildup of significant pools of organic matter and associated nutrients can enhance the ability of an ecosystem to recover after imposed natural or anthropogenic perturbations
Physical properties	
Stabilization of soil structure	Through the formation of bonds with the reactive surfaces of soil mineral particles, organic matter is capable of binding individual particles and aggregations of soil particles into water-stable aggregates at scales ranging from <2 μm for organic molecules through to mm for plant roots and fungal hyphae
Water retention	Organic matter can directly affect water retention because of its ability to absorb up to 20 times its mass of water and indirectly through its impact on soil structure and pore geometry
Thermal properties	The dark color that SOM imparts on a soil may alter soil thermal properties
Chemical properties	
CEC	The high-charge characteristics of SOM enhance retention of cations (e.g., Al^{3+}, Fe^{3+}, Ca^{2+}, Mg^{2+}, NH_4^+, and transition metal micronutrients)
Buffering capacity and pH effects	In slightly acidic to alkaline soils, organic matter can act as a buffer and aids in the maintenance of acceptable soil pH conditions
Chelation of metals	Stable complexes formed with metals and trace elements enhance the dissolution of soil minerals, reduce losses of soil micronutrients, reduce the potential toxicity of metals, and enhance the availability of phosphorus
Interactions with xenobiotics	Organic matter can alter the biodegradability, activity, and persistence of pesticides in soils
FIGURE 11.9 Conceptual representation of the contribution that SOM and its component fractions make to some of the soil properties to which organic matter makes a positive contribution. Changes in the width of the overall shape with changing clay content define the relative contribution made by organic matter to the function defined. Within each shape, the width of the various shadings defines the importance of each type of organic matter to the function defined. (Adapted from Krull, E.S., J.O. Skjemstad, and J.A. Baldock. 2005. Functions of soil organic matter and effects on soil properties, p. 107. Cooperative Research Centre for Greenhouse Accounting, Canberra, Australia.)

stabilize soil structure and also its biodegradability. In addition, the effects of SOM on soil properties often involve interactions with the soil mineral fraction. Thus, variations in SOM function across different soils may not be solely a consequence of qualitative or quantitative variations in the soil organic component but may also arise in response to changes in soil clay content. In Figure 11.9, an attempt has been made to conceptualize this idea using a series of shapes to illustrate the selective importance of SOM fractions in performing specific functions. In Figure 11.9, the width of the overall shape and that of the SOM components are meant to provide an indication of the relative importance to the function identified at the base of the figure. As the shapes widen, the relative importance increases and vice versa. Shapes have been used in this conceptual framework due to the absence of strong quantitative relationships linking SOM content and composition to the functions identified. The generation of quantitative relationships linking SOM content and composition to functions performed in soil should form the basis for future research projects.

11.4.1 Biochemical Functions

11.4.1.1 Reservoir of Metabolic Energy

The most fundamental function of SOM is the provision of metabolic energy, which drives soil biological processes and the direct and indirect effects, which this has on other soil properties and processes. Photosynthesis fixes CO_2 into glucose, which is then converted into a wide range of organic compounds (e.g., cellulose, hemicellulose, lignin, lipids, and proteins) by various enzymatic processes. The C fixed into such compounds is deposited in or on the soil during plant growth and as the plant or a portion of its tissues senesce, thereby providing C substrates for soil decomposer organisms. Oades (1989) presented an estimate of the C flow

through fertile grassland where primary production via photosynthesis was 10 Mg C ha^{-1} year^{-1}. Of the 3 Mg C ha^{-1} year^{-1} that was added to the SOC fraction, the soil fauna were estimated to utilize 0.3–0.45 Mg C ha^{-1} year^{-1}, while the soil microbial biomass was estimated to utilize 2.4 Mg C ha^{-1} year^{-1}. The majority of SOM processing is thought to be completed by the soil microbial biomass. However, other activities of the soil fauna enhance the ability of soil microbial decomposers to utilize organic residues added to soil. These include (1) fragmentation of plant debris, which enhances the surface area per unit weight of plant residue available to microbial attack and (2) distributing organic materials throughout the soil matrix, which provides an avenue for greater contact between decomposer microorganisms and substrates. Of the various SOM fractions, the POC fraction is suspected to play the biggest role in the provision of metabolic energy to decomposer populations.

11.4.1.2 Source of Macronutrients

A result of SOM decomposition is the conversion of macronutrients (N, P, and S) locked within organic chemical structures into inorganic forms, which are either immobilized and used in the synthesis of new tissues within soil organisms or mineralized and released into the soil mineral nutrient pool. With the exception of intensively managed soil receiving significant fertilizer inputs, organic matter provides the largest pool of macronutrients in the soil, with HUM being clearly the dominant fraction holding most macronutrients. McGill and Cole (1981) proposed that the mineralization of C, N, P, and S followed a dichotomous system involving both biological and biochemical mineralization. Biological mineralization is driven by the need of decomposer organisms for C as an energy source and accounts for the mineralization of N- and C-bonded S. Biochemical mineralization refers to the release of phosphate and sulfate from the P and S ester pool via enzymatic hydrolysis outside of the cell membrane. As a result and in contrast to organic N, organic P and S accumulation and mineralization in soils can occur independently of C and N dynamics.

11.4.1.2.1 Nitrogen

The soil N pool is dominated by N found in organic structures. In soils with significant contents of K$^+$-containing clay minerals (e.g., illite) capable of fixing NH$_4^+$, approximately 90% of the soil N is contained in organic structures, 8% exists as fixed NH$_4^+$, and 1%–3% can be found in the inorganic plant-available pool (NO$_3^-$ and NH$_4^+$). In soils with little capacity to fix NH$_4^+$ in clay minerals, the proportion of organic N is >97% and the inorganic fraction is 1%–3%. On a global scale, Söderlund and Svensson (1976) estimated that the organic N fraction of soils accounted for 95% of the total soil N pool, which is equivalent to the average value presented by Bremner (1968).

SON has been traditionally divided into the following five fractions based on a variety of acid hydrolysis procedures: (1) acid-insoluble N, (2) ammonia N recovered after hydrolysis, (3) amino acid N, (4) amino sugar N, and (5) hydrolyzable unidentified N. Data summarized by Stevenson (1994) for 11 studies where acid hydrolysis procedures were applied to different soil types showed that there was as much variation in the contents

of each form of N within similar soils as between different soil types. The proportions of each form of organic N were 7%–44% acid-insoluble N, 9%–37% ammonia N, 13%–50% amino acid N, 1%–14% amino sugar N, and 4%–40% hydrolyzable unidentified N. Although methodological differences may account for a portion of the large variations noted in the composition of SON, it is evident that approximately 50% of the total soil N cannot be identified by acid hydrolysis procedures (acid-insoluble N + hydrolyzable unidentified N).

Initial attempts to identify the chemical composition of unidentifiable organic N utilized gel filtration followed by acetylation and GC/MS (Schnitzer, 1985; Schnitzer and Spiteller, 1986). Schulten et al. (1995, 1997) used Curie-point—Py-GC/MS with N-selective detection of the pyrolysis products. These studies suggested that heterocyclic N compounds represented an important component of unidentified SON (see Schulten et al., 1997, for examples of the chemical structure of the heterocyclic N compounds). The formation of heterocyclic N compounds via non-biological fixation of $^{15}NH_3$ by humic substances (IHSS Suwannee River fulvic acid and peat and leonardite humic acids) and by reacting ^{15}N-labeled aniline with humic materials was noted by Thorn and Mikita (1992) and by Thorn et al. (1996), respectively. In contrast to these results, studies utilizing solid-state ^{15}N NMR spectroscopy have failed to observe substantial contributions from heterocyclic N, and spectra tend to be dominated by signals arising from amides and terminal amino groups (Clinton et al., 1995; Knicker and Lüdemann, 1995; Knicker et al., 1995). Further effort is required to address these inconsistencies and to quantitatively characterize the composition of the fraction of N, which cannot be identified by conventional acid hydrolysis procedures.

11.4.1.2.2 Phosphorus

The composition and cycling of soil organic P have been reviewed by Stevenson (1986, 1994) and Sanyal and Datta (1991). As a result of potential adsorption and inorganic precipitation reactions capable of reducing the availability of P in soils, mineralization of organic P is important to soil fertility (Tiessen et al., 1984; Beck and Sanchez, 1994). The relative importance of organic P as a nutrient source tends to be greater on highly weathered soils (Duxbury et al., 1989). The principal organic P-containing compounds in soils and their approximate proportions include inositol phosphates (2%–50%), phospholipids (1%–5%), nucleic acids (0.2%–2.5%), trace amounts of phosphoproteins, and metabolic phosphates (Stevenson, 1994). Soil organic P accounts for a variable proportion of the total soil P. Halstead and McKercher (1975) and Uriyo and Kesseba (1975) presented soil organic P values ranging from 4 to 1400 $\mu g\ g^{-1}$ soil, which accounted for 3%–90% of the total soil P. Uriyo and Kesseba (1975) derived the relationship between organic P and organic C given in Equation 11.8, which produces an organic C:P ratio of 115 and is consistent with the average value of 117 proposed by Stevenson (1994):

$$\text{Organic C } (mg\ g^{-1}\ \text{soil})$$
$$= 4.9 + 0.059 \text{ organic P } (mg\ g^{-1}\ \text{soil}) (R^2 = 0.49). \quad (11.8)$$

11.4.1.2.3 Sulfur

Reviews of the cycling and chemical composition of soil organic S include Stevenson (1986, 1994) and Nguyen and Goh (1994). Sulfur-containing organic compounds found in soils are generally grouped into two pools: compounds in which the S can be reduced to H_2S by hydroiodic acid (HI) and compounds in which the S is directly bound to C. The HI-reducible fraction consists mainly of ester sulfates (C–O–S bonds) and some ester sulfamates (C–N–S bonds). The C-bonded S fraction contains amino acid S (C–S bonds) or sulfonates (C–SO_3 bonds). The ester sulfates and sulfamates are typically associated with aliphatic side chains of soil organic compounds (Bettany et al., 1979), while the C-bonded S is incorporated along with C and N into the core of soil organic compounds and is generally less biologically accessible (McGill and Cole, 1981; Stewart and Cole, 1989). Organic S typically accounts for >90% of the total S found in nonsaline and nontidal soils (Nguyen and Goh, 1994; Stevenson, 1994).

11.4.1.3 Ecosystem Resilience

The resilience of an ecosystem can be defined as its capacity to return to its initial state after being subjected to some form of disturbance or stress (e.g., Webster et al., 1975; DeAngelis, 1980). The important role played by SOM in determining the resilience of an ecosystem can be exemplified by a comparison of the contents of chemical energy and nutrients stored within the soil organic fractions in several ecosystems. In temperate grasslands, high SOM contents result from large belowground additions of photosynthate, limited leaching, and slow decomposition rates. Storage of C in such ecosystems is greater in the soil than in vegetation (Szabolcs, 1994). The large store of chemical energy and nutrients contained in SOM offers resistance to the loss of soil fertility induced by natural or agricultural disturbance. Temperate grassland soils (e.g., mollisols) will remain agriculturally productive with limited inputs for many years, despite the mining of energy and nutrient reserves contained within SOM (Janzen, 1987; Tiessen et al., 1994). Such systems can be considered resilient, at least initially, but one must question how long such systems can be sustained. Tiessen et al. (1983) showed that rates of organic P mineralization in a grassland soil were in excess of crop requirements over the first 60 years of agricultural production. Subsequent to the first 60 years, only the less labile, low-energy-providing forms of organic matter remained, and organic P mineralization rates decreased below crop demand.

In temperate forests, SOM contents are less than that of temperate grasslands and more C and nutrients are stored in aboveground vegetation than in the readily available soil organic materials (Szabolcs, 1994). As a result, the impact of a natural disturbance such as fire can significantly deplete ecosystem stores of energy and nutrients, and ecosystem recoveries (resilience) are slow due to low residual contents of SOC and associated nutrients. Where temperate forests are cleared and agricultural production is initiated, SOM losses must be minimized; however, production systems that increase SOM and nutrient reserves (e.g., crop rotations including legume pastures) can lead to highly productive and sustainable agriculture.

In tropical forest ecosystems, the storage of energy and nutrients in vegetation dominates, and the rapid utilization of plant residues by decomposer organisms and cycling of nutrients maintain ecosystem stability. This, when coupled with the low stores of energy and nutrients in organic matter of tropical soils, indicates a reduced importance of SOM in ecosystem resilience (Anderson, 1995). A comparison of a temperate grassland mollisol with a tropical oxisol (Tiessen et al., 1994) demonstrated the important contribution of SOM to the resilience of the grassland soil and its reduced significance in the tropical soil.

11.4.1.4 Stimulation and Inhibition of Enzyme Activities and Plant and Microbial Growth

Research pertaining to the impacts of SOM on plants, microorganisms, and enzyme activities has typically used humic substances (e.g., humic and fulvic acids) as surrogates for SOM. The influence of humic and fulvic acids, tannins, and melanins on the activity of various enzymes was summarized by Ladd and Butler (1975), Müller-Wegener (1988), and Gianfreda and Bollag (1996). Based on earlier studies, Ladd and Butler (1975) concluded that the effect of humic acids on the activity of proteolytic enzymes varied and that the mechanism of humic acid–enzyme interaction involved primarily the carboxyl groups of humic acids. Inhibition of nonproteolytic enzyme activities by humic acids has also been demonstrated (Sarkar and Bollag, 1987). Müller-Wegener (1988) indicated that possible humic acid–enzyme interactions, which could impact on enzyme activity, included the following: (1) a direct interaction of the humic acid with the enzyme resulting in a modification of enzyme structure or changes in the functioning of active sites, (2) interference in the equilibrium of the enzyme reaction via the humic substances acting as analogue substrates, and/or (3) a reduction in the availability of cations, which often act as cofactors required for enzyme catalysis or structural stabilization of the protein molecule, by fixation on the humic acid molecule.

The influence of soil humic substances on plant growth and cellular activity have been reviewed (Chen and Aviad, 1990; Clapp et al., 2001; Varanini and Pinton, 2001; Nardi et al., 2002) and are generally attributed to direct (e.g., enhanced biochemical activity of plants) and indirect (e.g., increased efficiency of nutrient uptake) effects typically involve the absorption or adsorption of humic substances and the impact of these processes on biochemical properties at cell walls, cell membranes, and/or in the cytoplasm. Information on the impacts of humic materials in field studies is scarce and often confounded with other impacts of humic materials on soil properties (e.g., cation exchange capacity [CEC], nutrient status). Favorable effects on plants grown in defined media have included the following: (1) increased uptake of water and germination rate of seeds, (2) enhanced growth of shoots and roots as assessed by measurements of length and fresh and/or dry mass, and (3) increased root elongation, number of lateral roots, and root initiation (Nardi et al., 1996, 2002). Canellas et al. (2009) found that exposure of maize seedlings to solutions with 20 mg of humic acid carbon per liter for 7 days significantly altered metabolic activity and

enhanced root growth (length or density). Da Rosa et al. (2009) observed enhanced growth and K uptake by common beans when exposed to humic substances extracted from charcoal. Vaccaro et al. (2009) noted positive effects on growth and enzymatic activity of maize seedlings when exposed to the hydrophilic component or the entire soluble component extracted from a compost. Verlinden et al. (2009) noted an overall positive effect on dry matter yield and N uptake for a variety of plants (permanent grassland, maize, potato, and spinach) due to the application of humic substances originating from leonardite formations. Such positive effects on plant growth have been postulated to result from increased permeability of cell membranes, increased chlorophyll content, increased rates of photosynthesis and respiration, enhanced protein synthesis resulting from a stimulation of ribonucleic acid synthesis, and enhanced enzyme activity (Vaughan and Malcolm, 1985).

Addition of humic substances to soil can also influence the activity of soil microorganisms through the provision of a metabolizable source of carbon, increased nutrient supply, and enhanced permeability of cell membranes toward required solutes (Valdrighi et al., 1996). Addition of humic substances at concentrations ≤ 30 mg L^{-1} to a nutrient solution increased growth rates in microbial cultures (Visser, 1985). Humic acid addition was also found to stimulate in vitro growth and activity of aerobic nitrifying bacteria, but not actinomycetes or filamentous fungi (Vallini et al., 1993, 1997; Valdrighi et al., 1995, 1996). A greater promotion of microbial growth has been noted as the molecular weight of the added humic substances decreased (Garcia et al., 1991; Valdrighi et al., 1995). It has been suggested that interactions between added humic materials and microbial cell surfaces (Stehlickova et al., 2009) or humic materials and hydrophobic pollutants (Vacca et al., 2005) may be responsible for enhanced rates of decomposition and mineralization. Enhanced microbial activity due to the addition of humic substances is not always noted, particularly where the added humic substances form the sole source of available carbon (Filip and Tesarova, 2004). Whiteley and Pettit (1994) noted a decreased ability to decompose wheat straw in the presence of humic acid derived from lignite, and Yasmeen et al. (2009) observed that humic acids isolated from oil palm compost inhibited the mycelial growth indicating the presence of a fungicidal activity.

11.4.2 Physical Functions

11.4.2.1 Stabilization of Soil Aggregates

Organic matter is considered important to the maintenance of the structural stability of a wide range of soil types including mollisols, alfisols, ultisols, and inceptisols. Its importance tends to be less in oxisols and andisols, where hydrous oxides play an important stabilizing role, and in self-mulching soils (e.g., some vertisols), which contain clays with a high shrink/swell potential. In soils where organic matter is an important agent binding mineral particles together, a hierarchical arrangement of soil aggregates exists in which aggregates break down in a stepwise

manner as the magnitude of an applied disruptive force increases (Tisdall and Oades, 1982; Oades and Waters, 1991; Oades, 1993). Golchin et al. (1997a) and others have proposed the existence of three levels of aggregation: (1) the binding together of clay plates into packets <20 μm, (2) the binding of clay packets into stable microaggregates (20–250 μm), and (3) the binding of stable microaggregates into macroaggregates (>250 μm).

The importance and nature of the organic materials associated with each level of aggregation varies. At the scale of packets of clays, aggregation is primarily dictated by soil mineralogical and chemical properties important in controlling the extent of dispersion and is often a function of pedological processes. The binding together of clay packets to form microaggregates occurs via a range of mechanisms. The dominant mechanism is proposed to involve polysaccharide-based glues (mucilages or mucigels) produced by plant roots and soil microorganisms (Ladd et al., 1996). Emerson et al. (1986) presented transmission electron micrographs showing mucilage located between packets of clay plates. Small microaggregates (<53 μm) held together by humified organic matter and biologically processed materials are bound together around a particulate organic core (Oades, 1984; Elliott, 1986; Beare et al., 1994a; Golchin et al., 1994b) to produce larger microaggregates and small macroaggregates <2000 μm. Macroaggregates >2000 μm are stabilized by the presence of roots, fungal hyphae, and larger fragments of plant residues, which interconnect soil aggregates via bonding to aggregate surfaces, penetration into or through aggregates, and/or physical enmeshment (Tisdall and Oades, 1982; Churchman and Foster, 1994; Foster, 1994).

11.4.2.2 Water Retention

Organic materials can influence soil water retention directly and indirectly. SOM can absorb and hold substantial quantities of water, up to 20 times its mass (Stevenson, 1994). This direct effect, however, depends on the morphological structure of the organic materials and will not impart any beneficial effect to the soil unless it serves to enhance the ability of soil to hold water at potentials within the plant-available range. Organic matter in the form of surface residues can also influence water retention directly by reducing evaporation and increasing the infiltration of water.

The indirect effect of SOM on water retention arises from its impact on soil aggregation and pore-size distribution, and thus on plant-available water-holding capacity, AWHC, of the soil (the difference between volumetric water content at field capacity and permanent wilting point). This effect is best exemplified by the inclusion of SOC content as a significant parameter in pedotransfer functions, which predict pore-size distribution (e.g., Vereecken et al., 1989; da Silva and Kay, 1997; Kay et al., 1997). Equation 11.9 presents the pedotransfer function derived by da Silva and Kay (1997) to describe the relationship between volumetric water content, θ_v (m³ m⁻³), and matric potential, ψ (MPa), clay content, CL (%), organic C content, OC (%), and bulk density, BD (Mg m⁻³). Using this equation, Kay et al. (1997) calculated predicted changes in AWHC for soils ranging in clay content from 7% to 35% when organic C content was increased

by 0.01 kg kg⁻¹. Increases in AWHC of 0.039 and 0.020 (m³ m⁻³) were obtained for the soils with 7% and 35% clay, respectively, at a relative bulk density of 0.75. Application of the same equations to a data set acquired by Wegner et al. (1989) for 80 South Australian red brown earths (alfisols) showed that the increase in AWHC induced by increasing organic C content by 0.01 kg kg⁻¹ soil could be expressed by Equation 11.10. These results indicate that the presence of additional organic matter enhances AWHC of soils. Although the magnitude of the increase decreases with increasing clay content, building SOC content would be expected to be more difficult on a sand than on a clay soil:

$$\theta_v = a\psi_m^b, \qquad (11.9)$$

where

$$a = \exp(-4.15 + 0.68\ln CL + 0.42\ln OC + 0.27\ln BD),$$

$$b = -0.54 + 0.11\ln CL + 0.02\ln OC + 0.10\ln BD,$$

$$\text{Change in AWHC} = -0.0012(\%\text{clay}) + 0.055(R^2 = 0.82). \quad (11.10)$$

11.4.2.3 Soil Thermal Properties

The typical dark color of SOM contributes to the dark color of surface-mineral soils and can enhance soil warming and promote biological processes related to temperature in cooler climates (e.g., plant growth and mineralization of C and nutrients contained in SOM). However, the presence of litter layers or organic horizons can insulate a soil against fluctuations in air temperature and solar heating. On several Canadian forest soils subject to cold winters and cool springs, average soil temperatures and the growth of fertilized seedlings were greater where the litter layers were removed compared to where they were left intact (Burgess et al., 1995). Similar effects have been observed in a comparison of cropping systems, which leave different amounts of crop residue on the surface of the mineral soil (Fortin, 1993).

11.4.3 Chemical Functions

11.4.3.1 Cation Exchange Capacity

Organic matter contributes 25%–90% of CEC of the surface layers of mineral soils and practically all of the CEC of peats and forest litter and humus layers (Stevenson, 1994). The percent contribution is greatest for soils with low clay content or where the clay fraction is dominated by minerals with a low-charge density, such as kaolinite, and is lowest for soils with high contents of highly charged minerals, such as vermiculite or smectite. Organic matter will contribute most significantly to soil CEC in sandy soils.

The contribution of organic matter to soil CEC is pH dependent. At typical soil pH values (>5), the CEC of organic matter is derived principally from carboxyl functional groups, but phenol, enol, and imide groups may also contribute at higher pH values. Given that an increase in degree of oxidation is typically associated with decomposition of organic materials in soil, more

highly degraded organic materials would be expected to have a higher CEC than their less decomposed analogues. An increase in CEC was noted by Roig et al. (1988) during the degradation of manure over time. Beldin et al. (2007) measured the CEC of light and heavy soil fractions and found a positive correlation between CEC and %C for the light fractions but not for the heavy fractions, presumably due to the high content of mineral soil constituents that contribute to CEC in the heavy fractions (e.g., clay). The result from Beldin et al. (2007) and results obtained for black carbon by Liang et al. (2006) indicate that the different forms of SOM found in soil will contribute differently to CEC and that significant contributions can be made by the nonhumified components of SOM.

Beldin et al. (2007) also noted that predicted whole soil CEC values obtained by mathematically combining the CEC values measured for the light and heavy fractions on a mass basis were much greater than those measured for the whole unfractionated soils. The potential for carboxylic acid groups to be involved in organomineral interactions and the complexation of cations may reduce their ability to contribute to soil CEC. CEC measurements made on organic matter fractions isolated from soils must therefore be treated with caution, particularly where the potential exists to break organomineral associations and displace complexed cations during the fractionation process.

One approach used to assess the impact of SOM on soil CEC has involved performing CEC measurements before and after organic matter removal (Tan and Dowling, 1984; Thompson et al., 1989; Turnpault et al., 1996). However, this approach may result in an underestimation of the CEC of SOM since organic matter removal may expose inorganic CEC sites that were previously involved in organomineral interactions and not capable of contributing to whole soil CEC. Derivation of regression relationships between CEC and SOM/carbon has also been used to define the contribution of organic materials to soil CEC (Asadu et al., 1997; Oorts et al., 2003; Liang et al., 2006; Rashidi and Seilsepour, 2008; Seilsepour and Rashidi, 2008; Yimer et al., 2008). CEC values generated for SOM have ranged from 15 to >600 $cmol_c$ kg^{-1} C. As a general rule, each weight percentage of SOC contributes approximately 3 $cmol_c$ kg^{-1} soil (300 $cmol_c$ kg^{-1} SOC) to the CEC of neutral permanent charge soils (McBride, 1994) and approximately 1 $cmol_c$ kg^{-1} soil (100 $cmol_c$ kg^{-1} SOC) to the CEC of variable charge soils (Oades, 1989).

11.4.3.2 Buffering Capacity and Soil pH

The presence of weakly acidic chemical functional groups on soil organic molecules that can act as conjugate acid/base pairs makes SOM an effective buffer. The diversity in chemical composition of the functional groups (e.g., carboxylic, phenolic, acidic alcoholic, amine, amide, and others) provides organic matter with the ability to act as a buffer over a wide range of soil pH. James and Riha (1986) reported buffer capacities of 18–36 and 1.5–3.5 $cmol_c$ kg^{-1} (pH unit)$^{-1}$ for the organic and mineral horizons, respectively, of forest soils. Starr et al. (1996) obtained a good correlation between acid buffer capacity and organic matter content for 29 organic and 87 mineral soil horizons (E, B, and C horizons)

exhibiting buffering capacities of 9.8–40.8 and 0.1–5.2 $cmol_c$ kg^{-1} (pH unit)$^{-1}$, respectively. For 59 agricultural soil samples taken from the 0–15 cm layer of cultivated fields, Curtin et al. (1996) noted that titratable acidity could be described by Equation 11.11 in which the terms OC and clay represent the soil organic C and clay contents expressed in units of kg kg^{-1} soil and ΔpH is the reference pH (e.g., 8) minus the initial pH. Assuming the organic C content of SOM is 58%, Equation 11.11 indicates that the buffering capacity offered by organic matter was approximately 34 $cmol_c$ kg^{-1} (pH unit)$^{-1}$ and was an order of magnitude greater than that offered by clay (34 versus 3 $cmol_c$ kg^{-1} [pH unit]$^{-1}$). The average clay/organic C ratio for the soils studied by Curtin et al. (1996) was 7.9/1, indicating that even though most soils contained much more clay than organic C, organic C accounted for about two-thirds of the soil buffering capacity.

> Titratable acidity to pH 8
>
> $$= 0.02 + 59 OC \Delta pH + 3.0 \, clay \, \Delta pH \; (R^2 = 0.95). \quad (11.11)$$

Addition of organic matter to soil may result in increases or decreases in soil pH, depending on the influence that the addition has on the balance of the various processes that consume and release protons. A detailed presentation of these soil processes and their ability to release or consume protons is given by van Breemen et al. (1983). Factors that need to be considered include the chemical nature of the soil and that of the organic materials added as well as environmental properties including water content and extent of leaching. The net effect of adding organic matter to acidic soils is generally an increase in pH values (e.g., Yan et al., 1996; Pocknee and Sumner, 1997) with the main processes leading to the increase being (1) a decomplexation of metal cations, (2) mineralization of organic N, and (3) denitrification. Pocknee and Sumner (1997) found that on the acid Cecil soil, the extent of the increase in pH was controlled by the N content to basic cation content ratio. The decarboxylation of organic acids has also been shown to increase the pH of acid soils (Yan et al., 1996). Under alkaline soil conditions, however, these processes would be ineffective and would contribute to a reduction in soil pH as a result of their influence on soil CO_2 concentrations. The addition of organic matter to alkaline soils tends to acidify them especially under waterlogged and leaching conditions (Nelson and Oades, 1997). The main processes involved in the acidification of alkaline soils on addition of organic materials include (1) mineralization of organic S and P, (2) mineralization followed by nitrification of N, (3) leaching of the mineralized and nitrified organic N, (4) dissociation of organic ligands, and (5) dissociation of CO_2 during decomposition.

11.4.4 Complexation of Inorganic Cations

The presence of various functional groups on SOM provides the capacity for interaction with inorganic cations. Possible interactions can take the form of simple cation exchange reactions, such as that between negatively charged carboxyl groups

and monovalent cations, or more complex interactions where coordinate linkages with organic ligands are formed, such as occurs between amino acids and Cu^{2+} (Harter and Naidu, 1995; Baldock and Skjemstad, 2000). The influence that the complexation of inorganic cations by SOM has on soil properties and processes includes the following:

1. Altered solubility and degradability of associated organic materials (Skyllberg and Magnusson, 1995; Christl and Kretzschmar, 2007; Scheel et al., 2007)

2. Increased availability of insoluble mineral P through complexation of Fe^{3+} and Al^{3+} in acid soil and Ca^{2+} in calcareous soil, competition for P adsorption sites, and displacement of adsorbed P (Stevenson, 1994; Cajuste et al., 1996)

3. The release of plant nutrients through the weathering of rocks and soil parent materials by the removal of structural cations from silicate minerals (Robert and Berthelin, 1986; Tan, 1986)

4. Enhanced availability of trace elements in the upper portion of the soil profile as a result of upward translocation by plant roots and subsequent deposition on the soil surface and complexation during residue decomposition (Stevenson, 1994)

5. Facilitated adsorption of organic materials to soil minerals, which aids in the generation and/or stabilization of soil structure (Oades, 1984; Emerson et al., 1986)

6. Buffering of excessive concentrations of otherwise toxic levels of metal cations (e.g., Al^{3+}, Cd^{2+}, and Pb^{2+}; Anderson, 1995)

7. Pedogenic translocation of metal cations to deeper soil horizons (McKeague et al., 1986) and the formation of minerals (Huang and Violante, 1986)

11.5 Factors Determining the Content of Organic Matter in Soil

The amount of organic matter present in a soil is defined by the balance between the competing rates of input and loss of organic matter. Rates of input are typically defined by the amount of plant residue added to the soil. Any practice that enhances the amount of carbon captured by plants and the return of organic residues to the soil (above- and belowground) will increase inputs. For example, appropriate use of fertilizers to maximize productivity will also maximize returns of organic residues to the soil under any given management regime. Other factors such as the availability of water may place an upper limit on input rates by constraining potential plant productivity and thereby placing an upper limit on input rates. Where organic wastes are available (e.g., municipal green waste, residual materials derived from animal production, and biosolids), their application to soil can increase rates of input beyond that defined by environmental, soil, and management factors that normally limit plant production.

Losses of organic matter from soil result from decomposition and subsequent mineralization of organic carbon and its associated elements. Processes that accelerate decomposition increase the rate of loss. Additionally, losses of organic matter can occur through erosion or leaching. Erosion losses are rapid and event driven and may be catastrophic in localized areas. Losses by leaching are typically small compared to mineralization losses, but over time can lead to a significant removal or redistribution of organic matter within the soil profile.

During pedogenesis, organic matter accumulation in soil goes through a series of development phases. In the initial phase, a slow colonization by photosynthetic organisms occurs. A lack of available nutrients places a ceiling on the amount of CO_2–C that can be fixed. Low rates of carbon capture and low nutrient status limit both production and decomposition of SOM. Accumulation of SOM in this phase, expressed in units of g m^{-2}, proceeds slowly and can be aided by interactions with soil mineral components that are capable of biologically protecting SOM against decomposition. With continued soil development, SOM content and the activity of decomposer organisms increase to a point where a continued supply of nutrients in a plant-available form is reached. At this point, the rate of CO_2–C capture and organic matter deposition is greater than mineralization, and SOM accumulates at an exponential rate. With increasing SOM content, the ability of the soil to protect additional organic matter declines and an increasing proportion of added organic matter remains accessible to decomposition. As a result, the increase in organic matter content through time proceeds through an inflection point and then begins to decrease. Once the capacity for biological protection offered by soil mineral components is approached, the rate of mineralization of SOM tends toward the rate of deposition of fresh organic residues and SOM levels approach an equilibrium value. It is important to note that this biological protection rarely equates to a permanent and complete removal of organic C from the decomposing pool, but rather to a reduction in its rate of decomposition, when compared to similar materials existing in an unprotected state (Baldock and Skjemstad, 2000). As the older protected C is slowly mineralized, its position in the biologically protected pool is replaced with younger modern organic C.

The progression of SOM content with soil development and the magnitude of the equilibrium level of SOM will also depend on interactions, which occur between the factors of soil formation. Where cold and water-saturated soil conditions persist, decomposition is confined to slow anaerobic processes and organic matter contents expressed in units of gram per square meter may continue to increase leading to the formation of organic soils. In sandy soils, the extent of biological protection offered by the soil mineral component will be lower than that offered by clay-rich soils and large differences in SOM content can develop. Therefore, with the exceptions of peatland and wetland soils, which have been estimated to accumulate 0.1–0.3 Pg C $year^{-1}$ globally (Post et al., 1990), organic matter levels in soil do not increase indefinitely but rather tend to equilibrium values dictated by the soil-forming factors of climate, biota (vegetation and soil organisms), parent material, and topography (Baldock and Skjemstad, 1999; Six et al., 2002).

An additional factor that must be considered in an examination of factors influencing organic matter contents in soils used for agriculture and forestry is land management practice. Land management can induce rapid and drastic changes to equilibrium contents of SOM attained under natural undisturbed conditions and completely override the influence of soil-forming factors. For example, the conversion of native ecosystems to agriculture often, but not always (Skjemstad and Spouncer, 2003), results in a net loss of SOM (Mann, 1986; Davidson and Ackerman, 1993; Paustian et al., 1997b).

When measurements of SOM are conducted on perturbed systems, it must be acknowledged that they may still be in the process of attaining a new equilibrium content. When combined with the potential impacts that variations in climatic conditions can have, it can be difficult to detect the true direction of SOM change induced by alterations to land use at timescales <10 years. In fact, more than 50 years may be required to reestablish equilibrium conditions representative of a new land use (Baldock and Skjemstad, 1999). Combining this observation with early results presented by Jenny (1930) suggests that the relative importance of the soil-forming factors on SOM content can be viewed as management > climate > biota (vegetation and soil organisms) > topography = parent material (Baldock and Skjemstad, 1999).

An independent evaluation of the influence of any single factor on SOM contents is difficult because of the requirement that all other factors remain constant. Variations in the soil-forming factors experienced on a landscape scale and the interdependence of these factors contribute to the large variability noted for SOM contents, even within localized areas. When trying to assess changes of SOM content in a soil, it must be noted that rates of change in SOM (typically less than 0.5 Mg C ha^{-1} year^{-1}) are quite small compared to the large amounts of SOM often present (as high as 100 Mg C ha^{-1}, or more, in the top 60 cm soil layer; Ellert et al., 2008). Thus, changes in SOM can only be reliably measured over a period of years or even decades (Post et al., 2001). Since the distribution of SOM in space is inherently variable, temporal changes (e.g., attributable to management practices, environmental shifts, successional change) must be distinguishable from spatial ones (e.g., attributable to landform, long-term geomorphic processes, nonuniform management) to assess whether SOM is either increasing or decreasing (Ellert et al., 2008).

Computer simulation models of SOM dynamics, as defined through changes in SOC (Jenkinson et al., 1987; Parton et al., 1987; McCown et al., 1996), can be used to provide valuable information pertaining to the interaction of soil-forming factors on SOC levels and thus, ecosystem functioning, provided the models are structured appropriately. However, it is essential that field data are available to validate predictions (Burke et al., 1989).

11.5.1 Climate

Climate impacts SOM content primarily through the effects of temperature, moisture, and solar radiation on the array and growth rate of plant species and the rate of SOC mineralization. Post et al. (1982) found that the amount of SOC was positively correlated with precipitation and, at a given level of precipitation, negatively correlated with temperature. Similar results were observed by Guo et al. (2006) in an analysis of factors controlling SOC in the United States using maps generated from the State Soil Geographical database (STATSGO). Guo et al. (2006) found that SOC content increased as the mean annual precipitation (MAP) increased up to 700–850 m and then fluctuated as the MAP increased further. When other variables were highly restricted, there was a clear decline in SOC with increasing temperature. In the Great Plains of North America, precipitation controls NPP and temperature is considered to exert its strongest control over rates of SOC mineralization (Parton et al., 1987; Sala et al., 1988; Burke et al., 1989). Ladd et al. (1985) compared the mean loss of ^{14}C-labeled plant residues from four soils in South Australia with that obtained by Jenkinson and Ayanaba (1977) for soils in England and Nigeria and observed a doubling of the rate of substrate C mineralization for an 8°C –9°C increase in mean annual temperature. An influence of temperature on decomposition can also be inferred from ^{14}C content of SOC, which showed a latitudinal gradient in the mean residence time of SOC (Bird et al., 1996).

The observed trend of decreasing SOC content with increasing temperature implies that the relative temperature sensitivity of decomposition is greater than that of NPP. Because of the strong interactions between temperature, water availability, and substrate quantity, it is difficult to assess the temperature dependence of decomposition without confounding effects. In a compilation of data extracted from controlled incubation studies where water limitations were avoided and a common substrate was used at all temperatures, Kirschbaum (1995) showed that the Q_{10} value (rate of change of a process with a 10°C temperature increase) of C mineralization from soil was greater than that for NPP developed by Lieth (1973), especially at temperatures <15°C. Increases in temperature, particularly when starting from temperatures <15°C, will enhance decomposition more than NPP. The greater sensitivity of carbon mineralization to climatic variation was also observed at a regional (Goulden et al., 1998; Saleska et al., 2003) and global scale (Hicke et al., 2002). Hicke et al. (2002) showed that the variability in NPP was considerably less than the variability in growth rate of atmospheric CO_2 using inverse modeling, suggesting that the cause of the year-to-year variability in carbon fluxes is largely from varying rates of respiration rather than photosynthesis.

Climate has also been shown to affect the chemical structure of SOC. Using Py-GC to characterize the chemical structure of SOC in a climosequence of nine New Zealand soils, Bracewell et al. (1976) observed significant correlations between changes in the intensity of peaks in the chromatograms and MAP and temperature. By including both temperature and precipitation in a regression analysis, the resultant regression line explained 90% of the variation in chromatogram peak intensities. Amelung et al. (1997) used 10 grassland samples originating from different climatic zones of the North American Great Plains to investigate the impacts of mean annual temperature and precipitation on the chemical structure of SOC using a combination of chemical

methods and ^{13}C NMR. MAP was capable of accounting for only 10% of the variation in alkaline CuO oxidizable lignin. Higher precipitation tended to favor an accumulation of polysaccharide carbon; however, at a given MAP, polysaccharide carbon tended to decrease with increasing temperature. Amelung et al. (1997) suggested that the increased content of polysaccharide carbon in more humid conditions may have resulted from (1) a positive feedback mechanism in which increased plant production enhanced microbial activity and soil structural conditions, thereby offering the potential for protecting microbial polysaccharides within aggregates, and/or (2) an enhanced activity of earthworms that elevated polysaccharide content relative to the surrounding soils (Guggenberger et al., 1995) and offered organic carbon some physical protection against mineralization (Lavelle and Martin, 1992). Accompanying the decrease in polysaccharide carbon noted with increasing temperature, Amelung et al. (1997) further noted an increase in aliphatic carbon content. This accumulation of alkyl carbon at high temperature may be explained by (1) enhanced mineralization of carbohydrates and selective preservation of plant or microbially derived alkyl structures by adsorption onto clay particles (Baldock et al., 1989, 1992) and/or (2) higher inputs of plant-derived alkyl carbon in plant residues due to the presence of thicker cuticles on plants growing in warmer climates.

In a study using a soil sequence along an elevational gradient ranging from subtropical to subalpine climate zones in the Etna region (Sicily, southern Italy), Egli et al. (2007) examined changes in SOC and C:N ratios. Egli et al. (2007) showed that the concentration of SOC in the topsoil, the stocks of SOC in soil profile and the nature of the SOC were strongly related to elevation and, thus climate and vegetation. However, the C:N ratio in the topsoil was more defined by the vegetation type. A better protection of SOC at lower altitude was found and suggested to be an effect of the specific climate conditions with more pronounced change in periods of humidity alternating with periods of drought and resultant fire activity. Repeated bushfires had played a significant role in the soil formation as indicated by the presence of aromatic compounds and charcoal (Egli et al., 2007).

11.5.2 Soil Mineral Parent Materials and Products of Pedogenesis

The mineral phase of soils can exert a strong influence on SOM contents as a result of mechanisms capable of protecting organic materials against biological attack (Baldock and Skjemstad, 2000). Each soil has a given capacity to protect SOC dictated by the following:

1. The chemical nature of soil minerals
2. The presence of multivalent cations and their ability to form complexes with organic molecules in soils
3. The adsorptive capacity of soil minerals for organic materials as governed by particle size and surface area
4. Physical protection mechanisms, which restrict access of organic materials to biological attack, that is, the architecture of the soil matrix

The degree and amount of protection offered by each mechanism depends on the chemical and physical properties of the mineral matrix and the morphology and chemical structure of the organic matter. Furthermore, as with other aspects of SOC dynamics, strong interactions can exist between these characteristics (e.g., the presence and type of multivalent cations will undoubtedly be related to the chemical nature of the minerals present). Finally, each mineral matrix will have its unique and finite capacity to protect organic matter. In the extreme case where mineral protection mechanisms are not present, such as in well-aerated peat or forest litter layers, decomposability will be controlled by the recalcitrance offered by the chemical structure of the SOM itself.

11.5.2.1 Chemical Nature of the Soil Mineral Fraction

An analysis of different soil types indicates that soils with high contents of calcium carbonate ($CaCO_3$) and amorphous Al and Fe tend to have higher organic C contents compared to other soil types (Spain et al., 1983; Oades, 1988; Sombroek et al., 1993). In a study of the influence of soil properties on SOC genesis, Duchaufour (1976) suggested that the presence of calcium carbonate in a rendzina could protect both particulate organic and HUM carbon. Thin carbonate coatings visible under magnification and a precipitation of organic molecules induced by Ca^{2+} complexation were implicated in the protection of POM and HUM, respectively, and helped to explain the observed impedance of mineralization. Protection of SOC in high-base-status soils with less reactive or low contents of calcium carbonate results predominantly from the formation of Ca-organic linkages. In such soils, the initial decomposition of plant residues is rapid, but the subsequent utilization of initial decomposition products is slow leading to higher SOC contents, lower C:N ratios, and longer retention times. Soils with high base status typically have higher clay contents, are more fertile, and have greater annual vegetative inputs than similar low-base-status soils. Establishment of causative relationships between base status and SOC contents must therefore be examined carefully because of the potential confounding effects of increased vegetative inputs and protection mechanisms involving clay minerals.

Soils derived from volcanic ash (andisols) are typically characterized by large accumulations of SOC, high C:N ratios, and high allophane contents. The formation of Al-organic complexes is considered to be important to the biological protection of organic C in andisols. Boudot et al. (1986, 1988) obtained a significant correlation between the amount of native C mineralized from 10 French highland soils and the contents of amorphous Al and allophane, without observing significant correlations with clay content, exchangeable Al^{3+}, or crystalline iron oxides. Decreased organic C mineralization rates from ^{14}C-labeled organic substrates in allophanic soils and nonallophanic soils amended with allophane, relative to that noted in unamended nonallophanic soils, also demonstrated a protective effect of allophanic material on SOC (Zunino et al., 1982; Boudot et al., 1988, 1989). Zunino et al. (1982) demonstrated that the influence of allophane on mineralization of C from an organic substrate

varied with the chemical structure of the substrate. The presence of amorphous Fe compounds and Fe^{3+} cations has been shown to have a similar effect to that of allophane and Al^{3+} cations on the mineralization of C from organic materials; however, the magnitude of the protective effect was reduced (Boudot et al., 1989).

11.5.2.2 Impacts of Multivalent Cations

The presence of multivalent cations in soil has important implications on the behavior of clays and organic materials and the biological availability of organic C. When saturated with multivalent cations, clays remain flocculated, which reduces exposure of organic materials adsorbed onto their surfaces (Section 11.5.2.3) and macromolecular organic materials bearing functional groups become more condensed (altering their 3D structure) and thus less susceptible to the enzymatic attack.

The dominant multivalent cations present in soils include Ca^{2+} and Mg^{2+} in neutral and alkaline soils and hydroxypolycations of Fe^{3+} and Al^{3+} in acidic, ferrallitic, and andic soils. A protecting effect of Ca^{2+}, relative to Na^+, on organic C mineralization was effectively demonstrated by Sokoloff (1938), where the extent of mineralization and solubility of organic C in two soils was reduced by the addition of Ca^{2+} salts and enhanced by the addition of Na^+ salts. Other studies have also shown a decreased solubility of SOC in the presence of Ca^{2+} (Muneer and Oades, 1989c) and reduced mineralization of native organic materials and organic substrates on the addition of Ca^{2+} in incubation studies (Linhares, 1977; Muneer and Oades, 1989a, 1989b). In such studies, the question remained as to whether the effect of Ca^{2+} addition on mineralizable C resulted from an indirect effect on colloidal dispersibility or from a direct effect of Ca^{2+} complexation on the biodegradability of the organic molecule.

A direct effect of multivalent cation complexation on biodegradability in soil has been demonstrated by the following results:

1. A reduced oxygen absorption on incubation of humic acids saturated with Ca^{2+}, Al^{3+}, or Fe^{3+} in the same soil, relative to that noted for Na^+-saturated humic acids (Juste and Delas, 1970; Juste et al., 1975)
2. An increased protection of Al^{3+} and Fe^{3+} forms of plant and microbial polysaccharides (Martin et al., 1966, 1972)
3. A threefold increase in the amount of C mineralized from an organic soil after replacing Ca^{2+} cations with K^+ during a 25 week incubation (Gaiffe et al., 1984)

Indirect evidence for the involvement of cations in the accumulation of SOC can also be obtained through a comparison of the organic C contents of a variety of soil types. Using data derived from Spain et al. (1983) for the organic C contents of 29 Australian great soil groups, Oades (1988) showed that, excluding soils subject to waterlogging, there was a positive correlation between SOC contents and either high base status or the presence of substantial contents of Al and Fe oxides. Of interest was the comparison of siliceous and calcareous sands, which have little or no clay, but indicate an increased SOC content in the presence of Ca^{2+}-containing mineral fractions (<0.5% to 1.5% versus 1.5% to >4% organic C, respectively.)

11.5.2.3 Adsorption of Organic Materials onto Mineral Surfaces

Clay particles provide a reactive surface onto which organic materials can be adsorbed, and it is generally accepted that such adsorption reactions provide a mechanism of protecting SOC against microbial attack. The mineralogy, surface charge characteristics, and precipitation of amorphous Fe and Al oxides on clay mineral surfaces give clay minerals the capacity to adsorb organic matter and protect it from biological degradation. Correlations between SOC and clay contents have been observed (Schimel et al., 1985a, 1985b; Spain, 1990; Feller et al., 1991), and the various interactions between soil clays and organic materials have been summarized by Oades (1989). Such interactions are principally defined by the chemical nature of organic materials (functional group content, molecular size, etc.) and the type of clay mineral (kaolinite, illite, smectite, etc.). Numerous studies utilizing isotopically labeled organic substrates have shown a positive relationship between the contents of residual substrate C and soil clay content (Amato and Ladd, 1992). Clay particles have also been observed to encapsulate particles or patches of SOM (Baldock, 2002).

Not only the amount of clay, but also the specific surface area (SSA) of the clay and more generally the soil mineral particles is of importance. For example, Ransom et al. (1998) showed that adding even small amounts of high-SSA (100 m^2 g^{-1}) clay-size (<2 μm) material can have a significant effect on the total SSA of mineral particle mixtures. It must be noted that the relative magnitude of the effect of adding high-SSA clays to nonclay mineral particles decreases as the size of the nonclay mineral particles decreases (Baldock and Skjemstad, 2000).

In a field experiment where ^{14}C-labeled plant residues were added to four cultivated soils varying in clay content (5%–42%) but having similar clay mineralogy, climatic conditions, and no other organic inputs, the amounts of residual ^{14}C and total organic C in the topsoil (0–10 cm) remaining after 8 years of decomposition were nearly proportional to soil clay content (Ladd et al., 1985). Saggar et al. (1996) completed a similar study in which the decomposition of ^{14}C-labeled ryegrass was monitored over 6 years in four soils having variable clay content (16%–60%) and clay mineralogy. The mean residence time of the ^{14}C-labeled ryegrass was not related to clay content but rather to the SSA as measured by adsorption of *p*-nitrophenol. The increase in mean residence time with increasing SSA, suggested that the protective capacity of the soils toward transformed metabolites derived from plant residues was principally controlled by adsorption onto soil surfaces. Since the data presented by Ladd et al. (1985) were derived from soils with a similar clay mineralogy, SSAs would have been well correlated with clay content. The importance of available surface area was also suggested by the results of Sørensen (1972, 1975) where the addition of high-SSA montmorillonite to a soil/sand mixture protected microbial metabolites, but the addition of low-SSA kaolinite had little influence.

Hassink (1997) found a relationship between the silt- and clay-associated C and soil texture, whereas this relationship

did not exist for the C in the sand-sized fraction (i.e., POM C) suggesting that the capacity of soil to preserve C was linked to silt and clay particles. Using data from Hassink (1997), Six et al. (2002) were able to define significantly different relationships for 1:1 clays versus 2:1 clays, demonstrating the effect of clay type in C protection. Clearly, 1:1 and 2:1 clays have significant differences in CEC and SSA that may lead to a different capacity to adsorb organic materials.

SSA and mineralogy have been identified as key components in the preservation of organic matter in marine sediments (Keil et al., 1994; Mayer, 1994a, 1994b). Based on data generated in these studies, Ransom et al. (1998) showed that total organic carbon in the marine sediments was linearly related to SSA as well as to the content of high surface area minerals present. All these results suggest that the potential protective capacity of soil mineral particles, and more specifically that of the clay minerals, is more a function of the SSA available for adsorption of SOC than the absolute amount of clay.

The protective effect of mineral surfaces can also be shown experimentally by removing the minerals associated with the various fractions as defined by Skjemstad et al. (1999) with HF, since HF is known to dissolve soil minerals with little alteration to the composition of organic matter. In a recent experiment conducted by the authors, incubation studies were used to compare the mineralizability of HF- and non-HF-treated fractions of SOM (unpublished data, Figure 11.10). Mineralizability was defined as the cumulative amount of CO_2–C emitted per gram of organic C present in the sample being incubated. CO_2–C emissions were quantified by repeatedly sampling and then refreshing the headspace of an incubator system for up to 70 days using infrared detection of CO_2–C. Comparison of the mineralizability of SOC with and without HF treatment revealed an increased mineralizability with destruction of soil minerals consistent with the ability of minerals to stabilize a portion of the SOC against biological attack. The magnitude of the difference between the

non-HF- and HF-treated soils provides an assessment of the relative importance of mechanisms of mineral protection in defining the biological stability of the SOC present.

11.5.2.4 Physical Protection within Soil Matrix Offered by Soil Architecture

The architecture or structural condition of a soil can exert significant control over processes of biological decomposition through its effects on water and oxygen availability, dynamics of soil aggregation, and by limiting the accessibility of SOC to decomposer microorganisms and of microorganisms to their faunal predators. This limitation results from the ability of clays to encapsulate organic materials (Tisdall and Oades, 1982), the burial of SOC within aggregates (Golchin et al., 1997a, 1997b), and the entrapment of SOC within small pores (Elliott and Coleman, 1988; Strong et al., 2004). As outlined by van Veen and Kuikman (1990) and Hassink (1992), evidence of the importance of these processes in the protection of SOC in soils can be inferred from the following observations:

1. A faster turnover rate of organic substrates in liquid microbial cultures relative to that of similar substrates in mineral soils
2. An enhanced mineralization of C and N when soils are disrupted prior to incubation
3. A more rapid mineralization of organic C and plant residues in sandy soils than clay soils

A continuum of pore sizes exists in soils, starting with large macropores (>20 μm) and decreasing to micropores (<0.1 μm). Kilbertus (1980) suggested that bacteria can only enter pores >3 μm, which suggests that a significant proportion of the soil pore space may not be accessible to microbial decomposers. Organic materials adsorbed onto clay particles contained in pores <3 μm would only be decomposed as a result of diffusion of extracellular enzymes released by microorganisms followed
FIGURE 11.10 Change in mineralizability of <53 μm SOC fractionated from two different Australian soils induced by pretreatment with 2% HF according to Skjemstad (1994).

by a diffusion of the products of enzyme reactions back to the microorganisms (see Section 11.1). With increasing soil clay content, the proportion of the total soil pore space contained in micropores increases, and the potential for protection due to the exclusion of soil microorganisms increases. This concept of exclusion can be extended to the predation of microorganisms by soil fauna. van der Linden et al. (1989) suggested that protozoa and nematodes are excluded from pores <5 and <30 μm, respectively. Killham et al. (1993) showed that although placing glucose into pores <6 or <30 μm did not impact the rate of glucose decomposition, the turnover of glucose C incorporated into the microbial biomass was slower where glucose was only added to pores <6 μm. Strong et al. (2004) showed that decomposition occurs faster in soils with a large volume of pores with neck diameters of 15–60 μm. Their observations pointed to particularly rapid rates of decomposition near the air–water interface, most likely because of the ideal conditions for the organisms' mobility, nutrient or toxin diffusion, and oxygen supply. Furthermore, they suggested that on the one hand, SOC in large air-filled pores decomposes more slowly than in intermediate-sized pores (most likely due to decreased organism mobility, diffusion of solutes, and intimacy of contact between SOC and soil minerals) whereas on the other hand, the carbon trapped in the smallest pores was physically protected against decomposition.

The ability of clay particles to adsorb organic materials can also contribute to a biological protection of SOC through encapsulation and the formation of stable aggregates. Encapsulation of particulate organic residues in soils not only places a physical barrier between decomposer organisms indigenous to soils and potential substrates, but can also limit the movement of water and oxygen to sites of potentially active decomposition. A similar situation develops within soil aggregates. Relative to the larger pores between aggregates, the smaller pores within aggregates are more likely to remain filled with water during drying events, and therefore restrict oxygen movement into the aggregate. The presence of organic cores in aggregates (Beare et al., 1994a, 1994b; Golchin et al., 1994a, 1997a) will serve to increase this effect by enhancing oxygen consumption within the aggregate. It has been found that anaerobic conditions can exist in the core of moist aggregates even under well-aerated conditions (Sexstone et al., 1985). Smaller decomposition rates of SOC enclosed within soil aggregates compared to SOC located outside of soil aggregates have also been shown (Sollins et al., 1996; Angers et al., 1997). In native grasslands, Amelung and Zech (1996) demonstrated that the exterior 0.5 mm of >2 mm diameter peds contained less SOC and had a higher C:N ratio, less lignin, and more microbial-derived saccharides than ped interiors. The SOC associated with ped surfaces, therefore, appeared to turn over more rapidly and exhibited a greater degree of decomposition than that contained within peds.

Soil aggregation is a transient property and aggregates are constantly being formed and destroyed. Quantitative data on soil structural dynamics are, however, lacking. Recently, De Gryze et al. (2005) were able to define a macroaggregate turnover time of 40–60 days using data from a 3 week incubation experiment

and a model assuming an aggregate formation rate proportional to the respiration rate. There was no evidence that aggregate formation differed amongst the three soils examined, which all had a different structure. A subsequent study (De Gryze et al., 2006) confirmed this finding and showed that soil texture affected aggregate stabilization rather than aggregate formation.

11.5.3 Biota: Vegetation and Soil Organisms

11.5.3.1 Vegetative Inputs: Variations across and within Ecosystems

Vegetation influences SOC content as a result of the amount, placement, and biodegradability (chemical recalcitrance) of plant residues returned to the soil. Plant residues can be considered the dominant input and thus the primary source of organic carbon into or onto soils (Kögel-Knabner, 2002). Organic molecules created by the soil fauna and microorganisms are the secondary source of decomposable organic carbon in a soil. The greatest effects of vegetation on SOC contents are confined to the A horizon. Concentrations of organic C detected below the A horizon result from a combination of plant input through roots as well as pedogenic processes, which occur over longer timescales. Volkoff and Cerri (1988) showed that for Brazilian soil profiles, current vegetative cover was only in direct equilibrium with topsoil (A horizon) organic C, while that in subsoils was largely unaffected by the nature of vegetative cover. Once the SOC moves to depth (e.g., argillic or spodic horizons), it becomes less accessible to decomposer organisms, as exemplified by the increased depletion of ^{14}C with soil depth (Pressenda et al., 1996).

Scharpenseel et al. (1992) provided estimates of the amount of organic C contained in the vegetation, soil, and annual litterfall associated with various ecosystems (Figure 11.11). Across the tropical, temperate, and boreal forests, a continuous decrease in the amount of plant biomass and litter C is noted, with little change in the amount of organic C stored in soils. The decrease in the ratio of plant biomass C:SOC was associated with an increase in turnover time from 18 to 60 years. Presumably, most of this variation was related to the effect of temperature on litterfall decomposition; however, significant changes in litterfall quality and morphology are also evident. The amount of residue returned to the soil under similar types of vegetation appears to be a function of climatic factors, principally the amount of precipitation; however, this will depend on the nature of the factor most limiting plant growth. Where ample water is available, the amount of residues returned to the soil may be a function of some other factor such as nutrient supply. For example, it has been shown that P fertilization of Australian pasture soils can increase SOC by 150% or more relative to the native condition (Russel, 1960; Barrow, 1969; Ridley et al., 1990).

Where climatic and soil factors are constant, residue placement may become important. A comparison of the amounts of organic C contained in the plant biomass and soils of temperate grassland and forest ecosystems reveals that despite a much smaller amount of plant biomass in the grassland, annual litter C inputs, and SOC contents were approximately twice that of the
FIGURE 11.11   Variations in mean soil organic C contents, plant biomass C contents, and rate of litter deposition in various ecosystems. (From Scharpenseel, H.W., H.U. Neue, and S. Singer. 1992. Biotransformations in different climatic belts: Source sink relationships, p. 91–105. *In* J. Kubat (ed.) Humus, its structure and role in agriculture and environment. Elsevier Science Publishers, Amsterdam, the Netherlands.)

forests. The occurrence of deep organic-rich mineral horizons in temperate grassland soils (e.g., mollisols), in comparison with the concentration of organic materials in litter layers in boreal forest soil (e.g., spodosols), is an example of the influence that vegetation can have on SOC content and distribution within the soil profile. The apparent larger input of belowground residues in grassland soils compared to forest soils places organic C in close vicinity to the soil mineral components, thereby enhancing the potential for biological protection via the mechanisms discussed in Section 11.1.

The fate of surface-deposited residues depends on the activity of soil microorganisms and fauna and their ability to mix these residues into the surface-mineral horizons. In well-drained soils with high calcium status, the activity of earthworms and other soil fauna is high, leading to a mixing of organic residues through processes of particle-size diminution, ingestion and casting, and bioturbation. Under such conditions, a mull-type HUM layer is formed and litter layers do not develop. Plant residues and their decomposition products are intimately mixed with soil mineral particles, which facilitates potential biological protection through the various organomineral interactions, as discussed in Section 11.5.2. Soils low in calcium do not support as active soil faunal populations and plant residues tend to accumulate on the soil surface forming organic-rich, mor-type HUM layers. Within mor-type HUM, little potential exists for biological protection other than that due to the chemical recalcitrance of highly decomposed residues. The intermediate form of HUM is referred to as a moder.

11.5.3.2 Composition of Plant Materials: The Parent Material for Soil Organic C

Plant materials can be viewed as the parent material for SOC in much the same manner as we view primary minerals as the parent materials of soil mineral components. Plant materials are altered by soil fauna and microorganisms, predominantly after deposition in or on the soil, resulting in changes in the original chemical structure and in the synthesis of new compounds; just as some soil minerals dissolve and others precipitate during pedogenesis. An understanding of the chemical nature of plant materials is therefore important to studies of SOC genesis and composition. Kögel-Knabner (2002) provides a comprehensive review of the molecular composition of plant matter.

Plant materials consist of a range of different compounds varying in concentration across plant species, plant components (e.g., conducting, supporting, or photosynthetic tissues), growth stages, and space (distribution in the landscape). Plant cells can be divided up into three components, the cytoplasm, cell membranes, and cell walls. The cytoplasm contains the simple sugars, organic acids, amino acids, and enzymes essential to maintain metabolic activity. Cell membranes consist of globular proteins embedded within a lipid bilayer. Plant cell-wall components include hemicelluloses, celluloses, lignins, proteins, cuticular, and root waxes. Oades (1989) presented the following average contents for the major types of organic C in plant residues:

1. Extractable materials including water extractables (simple sugars, amino acids, and organic acids) and organic solvent extractables (free and bound alkyl molecules including fats, oils, and waxes)—200 g kg⁻¹
2. Hemicelluloses—200 g kg⁻¹
3. Celluloses—300 g kg⁻¹
4. Lignins—200 g kg⁻¹
5. Proteins—60 g kg⁻¹

The organic components of plant cell walls account for the majority of the mass of plant residues deposited in soils. Carbohydrate structures consist mainly of the polysaccharides cellulose and hemicellulose. Cellulose is the primary component of cell walls with a dominant structure of D-glucopyranose

Cellulose
D-glucopyranose residues linked by β-1,4-linkages

Noncellulosic polysaccharides (hemicellullose)
Pectin with α-1,4-linkages

Chitin
N-acetylglucosamine with β-1,4-linkages

Lignin precursors

Hydroxycinnamyl
alcohol   Coniferyl alcohol   Sinapyl alcohol

Examples of β-O-4-linked lignins

Guaiacyl   Syringyl   p-Hydroxyphenol

Cutin and suberin monomers

18-hydroxy-9-octadecenoic acid   9,10,18-trihydroxyoctadecanoic acid

$HOCH_2(CH_2)_7CH=CH(CH_2)_7COOH$

$HOCH_2(CH_2)_7CHCH(CH_2)_7COOH$

FIGURE 11.12   Representative chemical structures of the organic macromolecules found in plant and microbial residues entering the soil.

residues linked into a polymer via β-1,4-linkages (Figure 11.12). Cellulose can exist in either a crystalline or amorphous state as indicated by x-ray diffraction (Atalla and Vanderhart, 1984) and solid-state ^{13}C NMR (Vanderhart and Atalla, 1984). The crystalline state is more highly resistant to microbial and enzymatic degradation than the amorphous form (Ljungdahl and Eriksson, 1985). Hemicellulose is defined as the polysaccharide extractable in alkali solution. The hemicelluloses exist as linear and branched polymers of D-xylose, L-arabinose, D-mannose, D-glucose, D-galactose, and D-glucuronic acid monomers, which may be acetylated or methylated. Most hemicelluloses are composed of 2–6 of these monomers linked together primarily via a 1,4-β-linkage backbone as shown in Figure 11.12 for pectin, a glucuronic acid polymer.

Lignin represents the second most abundant organic compound in plant residues and accounts for approximately 5% of the mass of grasses and up to 30% of the mass of hardwood forest species (Haider, 1992). The basic building block of lignin, coumaryl alcohol, can be substituted with none, one, or two methoxyl groups at the C-3 and C-5 positions on the benzene ring to produce the p-hydroxyphenol, guaiacyl, and syringyl lignin monomeric units, respectively (Figure 11.12). The units are then linked together by more than 12 possible interunit linkages based on C–O or C–C bonds (McDougall et al., 1993). The major interunit linkage, accounting for about 60% of the linkages, is the β-*O*-4-linkage depicted in Figure 11.12 for the three lignin monomeric units. The nature of the lignin molecule changes with plant type: softwoods (gymnosperms) are dominated by

guaiacyl-based lignin, hardwoods (angiosperms) contain a mixture of guaiacyl- and syringyl-based lignin, and grasses are dominated by syringyl lignin. Results presented by Hedges et al. (1985) suggested that such changes in lignin composition can affect its biodegradability, with syringyl lignin being more susceptible to decomposition than guaiacyl lignin.

The protein and water-soluble components of plant residues, unless protected against biological attack, provide a readily decomposable substrate capable of supplying the chemical energy and nutrients required to drive soil biological processes. Enzymatic cleavage of the peptide linkages to form amino acids and mineralization of amino acid N to form NH_4^+ provide sources of N for soil biological processes, and the abiotic chemical processes, to be discussed subsequently.

Alkyl components of plant materials include free and bound lipids, polyesters, and nonsaponifiable alkyl C dominated biopolymers. Free and bound lipids represent a heterogeneous group of neutral and polar molecules, which are classified together based on their solubility in organic solvents (Tegelaar et al., 1989). The neutral component consists of triacylglycerols and waxes, which serve to protect external plant surfaces and to store energy. The polar component is dominated by the esterified fatty acids found in cell membranes. Insoluble polyesters, derived from hydroxy fatty acids, are found in cutin in plant cuticles and in suberin in roots. Cutin and suberin are composed of various long-chain (C_{16} and C_{18}), substituted fatty acids. The main substituent group is hydroxyl with lesser amounts of epoxy, ketone, and carboxyl groups also present (Holloway, 1982).

Two examples of cutin and suberin monomers are presented in Figure 11.12, and Tegelaar et al. (1989) have presented figures showing additional monomeric chemical structures and a proposed model of the structure of intact cutin and suberin. Plant cuticles and roots have also been shown to contain nonsaponifiable aliphatic biopolymers, which have been labeled cutan and suberan (Nip et al., 1986a, 1986b, 1987). Cutan and suberan are considered similar to cutin and suberin with the exception that they are highly cross-linked by nonester bonds.

In order to assess the influence of plant-residue composition on decomposition and mineralization, it is essential to remove other confounding effects such as climatic, soil, and biological parameters. In field studies, this can be accomplished by examining decomposition of all residues of interest at a single site. Vedrova (1997) assessed the impact of forest species on litter decomposition rates by placing litter collected from each species on small plots located within a single unforested site. Mean rates of mineralization measured for cedar, pine, larch, spruce, aspen, and birch litter over ≈2 years were 1.93, 1.57, 1.85, 2.20, 2.56, and 2.57 mg C g^{-1} litter C day^{-1}, respectively. A limitation of such studies is demonstrated, however, by the work of Elliott et al. (1993), in which the decomposition of four different forest litters (mixed hardwood, red pine, beech, and hemlock) was examined in each of the original four forest types. The rates of decomposition were principally a function of litter type, with mixed hardwood litter decomposing the fastest and hemlock litter the slowest. However, with the exception of the mixed hardwood litter, decomposition rates of the individual litter types were highest when they were placed in the forest type from which they were derived (i.e., decomposition of the hemlock litter was greatest in the hemlock forest). This interaction between litter type and forest type suggests that decomposition pathways in any given ecosystem may be tailored to the type of litter deposited. Thus, the results of decomposition studies where litters are removed from their ecosystem of origin, or where the community structure of the decomposer organisms is altered, may not accurately reflect the relative effects of residue composition on decomposability.

11.5.3.3 Relative Impacts of Soil Fauna and Microorganisms

The requirement of soil organisms for chemical energy and nutrients drives processes of heterotrophic decomposition in soils, which account for the major pathways through which SOC is mineralized. Abiotic chemical oxidation is unlikely to account for >20% of total C mineralization (Moorhead and Reynolds, 1989) and more often accounts for <5% (Lavelle et al., 1993). Microorganisms are the major contributors to soil respiration and are responsible for 80%–95% of the mineralization of C (Brady, 1990; Hassink et al., 1994). Hassink et al. (1994) calculated that the contribution of the fauna to C mineralization in two sandy and two loamy grassland soils to range from 5% to 13% of the total C mineralization. The pattern of C mineralization by the soil fauna through time differed from that of total C mineralization, suggesting that the activity of the soil fauna did not contribute substantially to the differences in total C

mineralization observed between the soils. Hassink et al. (1993) concluded that soil protozoa and nematodes did not significantly influence soil C mineralization despite a positive response of bacterivorous nematodes on the amount of N mineralized. Several other studies have shown that soil fauna enhanced nutrient mineralization had both positive and negative effects on SOC mineralization (Griffiths, 1994; Kajak, 1995; Alphei et al., 1996). In a study including protozoa, nematodes, and earthworms, Alphei et al. (1996) noted that none of the fauna studied significantly affected basal respiration. However, other studies showed that earthworm invasion can have a marked potential to alter (usually reduce) soil C storage on local and regional scales (Alban and Berry, 1994; Bohlen et al., 2004).

The role of soil fauna in decomposition processes should not be based only on their direct contribution to C mineralization. Soil fauna also act to reduce the particle size of litter, distribute it within the soil, transport otherwise immobile microorganisms to new sites within the soil matrix, and prime microorganism activities by the production of readily available substrates (e.g., earthworm intestinal mucus). In so doing, soil fauna generally enhance microbial activity and rates of decomposition. Soil conditions, which limit (e.g., water saturation and the development of anaerobic conditions) or enhance (e.g., tillage or installation of drains in imperfectly drained soils) the activity of soil microorganisms or fauna, will also impact significantly SOC mineralization rates and thus alter SOC levels.

11.5.3.4 Composition of the Microbial Community

The population of decomposer microorganisms in soil is extensive; densities up to 10^{10} bacteria and several kilometers of fungal hyphae per gram of soil have been measured in a wide range of soils (Lavelle et al., 1993). As a result of the diversity of decomposer organisms, the existence of interactions between specific types of organic residue and species of decomposer organisms can have pronounced effects on the chemical structure and biological availability of residual organic materials. The decomposition of woody materials provides an excellent example of how the species composition of the decomposer population can influence the chemical nature of decomposition products. Laboratory incubations of *Eucryphia cordifolia* wood with a brown-rot fungus (unidentified species) and a white-rot fungus (*Ganoderma australe*) showed a more selective utilization of carbohydrate C by the brown-rot fungus and a delignification by the white-rot fungus (Martínez et al., 1991). Using the same white-rot fungus in a solid-state fermentation procedure with beech wood, Martínez et al. (1991) noted little change in the chemical composition of the wood, despite a 36% mass loss. Barrasa et al. (1992) obtained similar results in an ultrastructural study. Selective delignification of *Laurelia philippiana* wood by the white-rot fungus *Phlebia chrysocrea* was noted, but decomposition of the same wood by *G. australe* resulted in increased lignin contents. The selective degradation of carbohydrates by brown-rot fungi appears to occur independently of the fungal or wood species involved. However, the presence of a selective or nonselective degradation process for white-rot fungi

appears to depend on interactions between the species of fungus and wood. Under anaerobic conditions, the activity of obligate aerobes such as wood-degrading fungi is limited and bacterial decomposition processes dominate. In examinations of buried woods, it has been found that decomposition processes invariably result in a preferential utilization of carbohydrates and a concentration of lignin (e.g., Bates and Hatcher, 1989; Bates et al., 1991). Such data indicate that changes in species composition of the decomposer community can significantly alter the decomposition processes and thus, rates of accumulation or loss of organic C from soils.

Earlier in this chapter, a conceptual framework to describe the controls over the decomposition process was presented (Figure 11.5) that was built around the concepts of biological capability and capacity. Various methods can provide information regarding the biological capability and capacity of decomposer communities and the way these properties can be affected by environmental parameters and management practices. For example, the potential degradative capabilities of decomposer communities can be measured using substrate utilization profiles based on Biolog plates (e.g., Bochner, 1989; Bucher and Lanyon, 2005) or microrespirometry like the MicroResp™ method (e.g., Campbell et al., 2003; Wakelin et al., 2008), which is a relatively recent method of community level physiological profiling (CLPP) and uses whole soil samples rather than soil extracts thereby eliminating extraction bias. Furthermore, the extraction and analysis of DNA and RNA (e.g., PCR-DGGE) from soils as well as phospholipid fatty acids (PLFA) can provide an indication of the genetic diversity and structure of soil microbial communities (Muyzer et al., 1993; Widmer et al., 2001; Crecchio et al., 2004; Wakelin et al., 2008). Several indices and multivariate statistical analyses can be used with these techniques to determine the influence of soil and environmental properties on the capability and capacity of the microbial community. Several factors have already been investigated like the influence of soil type (Schutter and Dick, 2000; Banu et al., 2004; Wakelin et al., 2008), crop rotation (Bending et al., 2004; Crecchio et al., 2004), application of various fertilizers (Bucher and Lanyon, 2005), vegetation (De Fede et al., 2001), and agricultural management practice (Wakelin et al., 2008). Although the methods have proven to be reproducible, different results between the different methods have been identified (Widmer et al., 2001). Therefore, it is recommended not to use these methods in isolation if a representative assessment of the composition of the microbial community is desired.

11.5.3.5 Relationship between Organic Residue Composition and Biochemical Recalcitrance

All organic C in soils can serve as a substrate. In addition to the potential mechanisms of biological protection of organic materials offered by the soil mineral fraction, the chemical structure of the organic residue itself can also impart a degree of biochemical recalcitrance. This biochemical recalcitrance of the potential substrate is defined by the strength of intra- and intermolecular bonds, the degree of polymerization and regularity of structural

units in polymers, and the content of aromatic and aliphatic functional groups (Baldock et al., 1997a; Gleixner et al., 2001). Rates of decomposition of known organic substances in soils were reviewed by Paul and van Veen (1978). Although variations in decomposition rates for any single substrate were evident as a result of differences in soils and incubation conditions, simple organic molecules and monomeric compounds decomposed most rapidly. Oades (1989) showed that the extent and rate of mineralization of C for a series of polysaccharides (glucose, dextran, cellulose, and a fungal polysaccharide) decreased with increasing molecular complexity and branching. Similar results were obtained by Martin and Haider (1975) for the mineralization of C from specifically ^{14}C-labeled benzoic and caffeic acid monomers and polymers. C mineralization was most extensive from carboxylic acid groups, less extensive from the aromatic ring C of the monomers, and least extensive from the polymeric aromatic ring C. Of the polymeric materials contained in plant residues, lignin and other polyphenolic C and aliphatic C appear to be the most recalcitrant, but, as discussed in the previous section, the stability of lignin C will be also related to the species composition of the decomposer community.

Many studies have demonstrated a relationship between decomposition and plant-residue characteristics thought to be indicative of residue quality (e.g., Edmonds and Thomas, 1995; Ågren and Bosatta, 1996; Cortez et al., 1996; Hobbie, 1996). Included in these residue characteristics are N concentration, C:N ratios, lignin and/or polyphenol concentration, lignin:nitrogen ratios, and acid-soluble carbohydrates (Heal et al., 1997). Ågren and Bosatta (1996) found that the proportions of extractable, acid-soluble, and acid-insoluble C obtained from a conventional chemical fractionation could be used to assess the quality of forest litter, particularly when the acid-insoluble fraction did not dominate.

During the decomposition of plant residues, significant changes in chemical composition of residual C are evident (Baldock et al., 1997a). In response to such changes, Berg and Staaf (1980) proposed a model of litter decay in which decomposition was controlled initially by N content but subsequently by lignin concentration. This was supported by the results of Edmonds and Thomas (1995), which showed that organic C mineralization rates from green needles of western hemlock and pacific silver fir were initially similar, but became more a function of litter chemistry (e.g., lignin:N ratio) as decomposition progressed.

11.5.4 Topography

Topography exerts its major control over SOC contents through a modification of climate and soil textural factors and through its impacts on the redistribution of water within a landscape. Soils in downslope positions are often wetter and have finer textures than soils in upslope positions or at the top of knolls. Topographic-induced changes in the soil microenvironment often lead to changes in plant communities (Sebastia, 2004), which in turn can influence the magnitude and quality of residue returns. Burke et al. (1995) examined the extent to which

SOC content varied at a landscape scale at two sites differing in soil texture but having similar climatic characteristics. Burke et al. (1995) noted increased organic C contents (and clay and silt contents) in downslope positions relative to the summits at both sites. Such a finding has been attributed to the downslope movement of organic C and organic-rich clay (Reiners, 1983). However, additional gradients in available water along slopes, especially in water-limited systems, influence plant production (Peterson et al., 1988), with greater biomass inputs and greater potential biological protection of organic C via higher clay contents at the base of slopes. Where excessive water exists, drainage of depressions in the landscape can be restricted, leading to the development of anaerobic conditions and a preservation of organic C relative to the better-drained higher landscape elements during wetter times of the year.

Guo et al. (2006) showed that the SOC decreases as elevation increases and that level topography had twice the SOC content of other slope classes. Particularly, in mountain areas that are by nature highly heterogeneous, taking topography into account is required to predict SOC stocks across the landscape. In a study investigating the SOC storage in mountain grasslands of the Pyrenees, Garcia-Pausas et al. (2007) found that the SOC stocks were particularly low at high altitudes probably as a result of an overall temperature limitation of NPP. Climatic and topographic variables were able to predict a significant part of the C storage variability in the mountain grasslands examined by Garcia-Pausas et al. (2007). The microclimate conditions related to topographic position (aspect and slope) were identified as important factors for predicting C storage in soils of the high-altitude grasslands and should be taken into account to achieve accurate estimations of C stocks in mountain ecosystems.

As a consequence of all the possible confounding factors, it is difficult to study the sole effects of topography. For example, the interactive effects of topography (depositional and erodible zones) and tillage (conventional versus minimum tillage [MT]) on the redistribution of C, N, and P within an agricultural landscape were examined by De Gryze et al. (2008). In general, organic matter content and moisture content were greater in lower, depositional areas compared to erodible areas, and the impact of topography on the stabilization and redistribution processes of nutrients was more pronounced in conventional tillage (CT) than MT. This last finding clearly demonstrates that interactions between topographic characteristics and land management practices should be considered in regional inventory assessments of SOC (De Gryze et al., 2008).

11.5.5 Land Management Practices

Paustian et al. (1997b) reviewed the influence of agricultural management practices on SOC levels. Hutchinson et al. (2007) summarized the relative rates of SOC change for a range of "carbon friendly" agricultural management treatments and found that most changes were <0.6 Mg C ha^{-1} year^{-1}. The influence of forestry management practices has also been reviewed (Johnson, 1992; Johnson and Curtis, 2001; Johnson et al., 2002).

The most dramatic influence of agricultural practices occurs when soils are first brought into production. Typically, SOC levels decrease for the first few decades after cultivation and then stabilize at a new equilibrium level, which is dictated principally by the ability of the soil to protect organic C and the amount, quality, and distribution of plant-residue inputs. For example, Haas et al. (1957) observed a loss of 28%–59% of the SOC following 30–43 years of cropping at 11 sites within the North American prairies. David et al. (2009) also measured reductions SOC (30%–50%) due to the conversion of prairies to annual cultivation and artificial drainage using archived samples and long-term resampling of soils.

The following characteristics of crop production systems, in comparison with those of native grasslands, help to explain the observed losses of SOC induced by cultivation:

1. 80% lower allocation of organic C to soils (Buyanovsky et al., 1987)
2. Reduced belowground allocation of photosynthate (Anderson and Coleman, 1985)
3. Enhanced aggregate disruption and exposure of physically protected organic C due to cultivation
4. Enhanced rates of decomposition of available organic C substrates due to more favorable abiotic conditions (e.g., aeration, temperature, and water content)

In practice, continuous alteration of land management and cropping practices (e.g., adoption of reduced tillage, the inclusion, or removal of pasture) will lead to a system where SOC levels are always in a state of flux, increasing with some practices and decreasing with others (Baldock and Skjemstad, 1999). Only if management practices are left in place long enough, it is possible to gain an indication of what the new equilibrium SOC value would be for any given land management system.

Field trials set up to examine the impact of fertilizer additions on SOC content, have revealed that the addition of N fertilizers typically enhances SOC contents. This is particularly true in temperate-zone ecosystems where N availability is thought to limit NPP (Peterson and Melillo, 1985; Schimel et al., 1996; Holland et al., 1997). Explanatory mechanisms suggest that N-fertilizer additions result in a greater return of plant residues to soils due to enhanced production, a reduction in decomposition rates due to enhanced soil drying (Andrén, 1987), a promotion of soil acidification (Thurston et al., 1976), a repression of lignolytic enzymes, and a formation of recalcitrant humic materials through the reaction of amino acids with humic precursors (Fog, 1988).

In tropical systems, the establishment of pastures after clearing of forests is widespread (Sombroek et al., 1993). Pasture establishment immediately after deforestation, using species with high proportions of belowground biomass, may increase SOC contents as demonstrated in the Brazilian Amazon (Serrâo et al., 1979), Latin America (Ligel, 1992), and East Africa (Boonman, 1993).

The intensity with which a soil is cultivated can impact both the total amount of SOC and its distribution with soil depth. No-till systems tend to concentrate residue inputs at the soil

surface and generally enhance soil organic C and N contents in soil surface layers (Angers and Eriksen-Hamel, 2008). To accurately evaluate the influence of tillage practices on SOC stocks, it is important to collect soil samples beyond the depth of tillage and to account for variations in soil bulk density. Paustian et al. (1997b) presented data from a number of long-term field trials indicating that SOC retention is typically enhanced under no-till relative to more intensive CT systems. However, in a review of Australian publications, Valzano et al. (2005) found that a positive effect of no-till or reduced till on SOC in the 0–30-cm soil layer could only be demonstrated at high annual rainfalls (>660 mm). Valzano et al. (2005) also noted that the separation of residue handling from the physical effect of passing an implement through the soil was difficult to separate given the wide range of residue handling practices associated with the different tillage systems.

11.6 Contribution of Soil Organic Matter to the Global Carbon Cycle

The organic carbon contained within SOM represents a significant reservoir of carbon within this global carbon cycle (Figure 11.13). SOC has been estimated to account for 1200–1550 Pg of C (1 Pg = 10^{15} g) to a depth of 1 m and for 2300–2450 Pg of C to a depth of 2 or 3 m (Eswaran et al., 1995; Jobbagy and Jackson, 2000; Lal, 2004a; Houghton, 2005). Comparative estimates of organic C contained in living biomass (550–560 Pg) and the atmosphere CO_2–C (760–780 Pg; Lal, 2004a; Houghton, 2005) indicate that variations in the size of the SOC store could significantly alter atmospheric CO_2–C concentrations. For example, a 5% shift in the amount of SOC stored in the 0–2 m soil profile has the potential to alter atmospheric CO_2–C by up to 16%.

Land-use changes can induce either a net emission or a net sequestration of organic carbon in soil depending on the resultant balance between losses and inputs. The net change in inputs and losses will be defined by the soil and environmental properties and land management practices discussed previously. Sequestration of organic carbon in soil is a slow process typically requiring decades, but is suggested to offer the most efficient natural strategy for offsetting increased atmospheric CO_2–C concentrations (Metting et al., 1999; Post et al., 1999; Lal, 2004b). Over the next century, improved land management strategies may have the capacity to sequester up to 150 Pg of CO_2–C (Lal et al., 1998; Lal, 2004a). Considerable uncertainty exists in such estimates because of an inability to accurately predict the potential sequestration of carbon that is possible in soil. Improving our understanding of SOC cycling processes and how these are affected by environment and land management practices will be vital to identify opportunities for building SOM and sequestering carbon in soils.

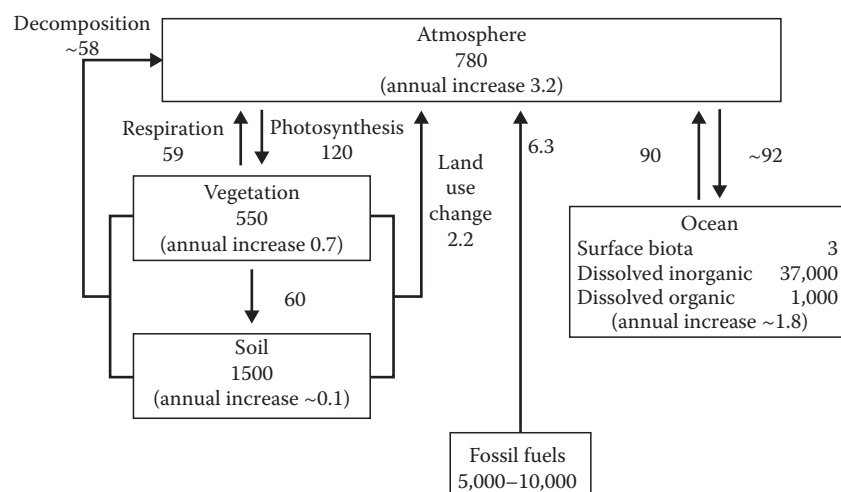
Estimates of the potential to sequester carbon in agricultural soils have been made for the United States (Lal et al., 1998), Canada (Bolinder et al., 2008), China (Han et al., 2005, 2006), the European Union (Freibauer et al., 2004; Janssens et al., 2005; Romanenkov et al., 2007), and South America (Cerri et al., 2004, 2006). Such estimates are typically based on the use of long-term field experiments or simulation modeling. Where estimates are based on field experiments, it is important to ensure that the potential for saturation of the soils capacity to protect carbon from decomposition is acknowledged and that measured carbon sequestration rates are not projected unimpeded into the future. A similar consideration must be applied to soil carbon simulation modeling activities. Most soil carbon models apply first-order kinetics to the decomposition of component carbon pools (Paustian, 1994). Therefore, predicted equilibrium carbon stocks are linearly proportional to carbon inputs (Paustian et al., 1997a, 1997b; Six et al., 2002), and modeling activities predict that unlimited increases in soil carbon stocks can occur provided inputs of carbon to the soil can continue to increase.


FIGURE 11.13 The global carbon cycle. All pool sizes are in units of Pg C and all fluxes are given in units of Pg C year^{-1}. (Adapted from Houghton, R.A. 2005. The contemporary carbon cycle, p. 473–513. *In* W.H. Schlesinger (ed.) Biogeochemistry. Elsevier Science, Amsterdam, the Netherlands.)

Since carbon inputs to soil will be limited by constraints placed on photosynthesis (e.g., availability of water, nutrients, heat, and ultimately light) and current soil carbon simulation models do not define a maximum soil carbon protective capacity, modeled estimates of potential carbon sequestration in soils need to be carefully scrutinized.

The concept of soil carbon saturation suggests that each soil has a unique carbon saturation level dictated by soil properties including texture, mineralogy, bulk density, and depth (Ingram and Fernandes, 2001; Six et al., 2002; Stewart et al., 2008a, 2008b). Soil carbon sequestration potential should therefore be estimated as the difference between the current and saturated soil carbon content. Defining soil carbon saturation values has proven difficult, although Hassink (1992) suggested that the amount of carbon obtained under long-term pastures may provide an indication. Furthermore, true soil carbon saturation values may be of limited importance if the inputs of organic carbon required to attain and maintain such levels are beyond the capture of carbon by photosynthesis and deposition within soil. Of more practical interest would be the behavior of soils as they approach their carbon saturation capacity as well as the influence of soil carbon saturation deficit on the efficiency of the SOC accumulation in saturated soils.

Although soil carbon does offer the possibility for sequestering atmospheric CO_2–C, the potential for soil carbon sequestration in soil is small compared to projected emission of CO_2 form current energy practices (about 150 Pg versus 600 Pg over the next 100 years). Soil carbon sequestration is also finite, an upper limit exists, and as soils move toward the upper limit, the rate of soil carbon sequestration will diminish. Enhancing soil carbon form atmospheric CO_2–C sequestration should therefore be viewed as a mechanism for "buying time" for the development and implementation of longer-lasting measures for reducing fossil fuel emissions (Watson et al., 2000; Houghton, 2005). However, it is also important to recognize that increasing sequestration of carbon in soils by building SOM may offer the added benefit of increased productivity through mechanisms discussed previously.

11.7 Summary

Soil organic matter is a complex mixture of a variety of materials derived initially from photosynthesis by plants but then altered through decomposition processes that enhance its diversity in composition. Such compositional diversity provides the SOM with the capability to contribute beneficially to the many functions that it serves in a soil. Key goals for future work on SOM should include the following:

1. An acknowledgment of the diversity in SOM composition and a development of fractionation systems capable of quantitatively dividing SOM up into biologically relevant components
2. Development of predictive relationships that quantify the role of each component to the various functions to which SOM contributes and an assessment of any soil type specificity that may exist
3. Parameterization of carbon cycling models build on measurable components and inclusion of the quantitative relationships between SOM composition and soil properties (functions) to allow the prediction of both SOM dynamics and the subsequent impacts on soil properties

With the potential for large-scale introduction of carbon trading schemes and a requirement to reduce the emission of greenhouse gases, a more complete understanding of SOM dynamics and how altering SOM will alter soil properties will be essential. Such understanding is required to develop viable land management practices that accommodate the potentially conflicting issues of maintaining food security for an increasing global population, ensuring profitability of individual farming enterprises, and enhancing the capture of atmospheric CO_2 as organic matter in soils while reducing emissions of other greenhouse gases (nitrous oxide and methane).

12
Soil Solution

Paul Schwab
Purdue University

The soil solution is the hub of chemical and biological activity in the soil. Most reactions are slow in the absence of water: Soil organisms become dormant or die, mineral transformations become imperceptibly slow, and soil chemical weathering and formation processes become greatly impeded. Addition of moisture to previously dry systems reinitiates these reactions.

12.1 Basic Concepts

12.1.1 Definitions

The simplest definition of the soil solution is "aqueous liquid phase of the soil and its solutes" (SSSA, 2009). A broader definition describes the soil solution as a natural system that is both open and dynamic. Its composition is the result of the concurrent reactions of the labile soil minerals, organic materials, and biological metabolism. Any discussion of the soil solution, however, must take into account that from physical, chemical, and biological perspectives, a significant fraction of the soil solution

seemingly does not participate in some important phenomena. Many examples exist in different disciplines of soil science that illustrate this point. In soil physics, the concepts of "mobile" and "immobile" water have been introduced to explain why water is often observed to move more rapidly through soil than would be predicted assuming that water participates in the transport process. Higher plants and microorganisms undergo serious moisture deficit even when measurable water still exists in the soil. The composition and kinetics of reaction of water very near solid surfaces in the soil are significantly different than in the bulk solution. Therefore, a more functional definition of soil solution goes beyond simply the "aqueous liquid phase" and reflects that the soil solution may be dependent upon the application and, in some instances, the methodology used to obtain this solution from the soil.

From the viewpoint of a soil chemist, the soil solution may be defined as "the aqueous liquid phase in soil with a composition that is influenced by exchanges of matter and energy with soil air, soil solid phases, the biota, and the gravitational field of the

earth" (Sposito, 2008). By defining it as a phase, Sposito implicitly requires that the soil solution has uniform bulk properties (such as composition and temperature) and can be isolated from the soil. The requirement of uniformity can be met only on small scales of time and space because of the dynamic and spatially variable nature of soils.

The soil solution viewed on a molecular level would reveal that it is not a distinct entity but a part of the

> continuum of phases exhibiting indistinct interfaces at the molecular level. Solutes in the aqueous phase may be associated with bound water at the surfaces of soil colloids, free water percolating through soil macropores, water in the free space of plant roots, or immobile water in soil micropores.
>
> **(Wolt, 1994)**

12.1.2 Composition

Because soil solutions are highly variable over space and time, their composition can be discussed only in general terms. Trends in relative concentrations of soluble inorganic and organic constituents (see Chapter 11) are similar for most soils, but natural and anthropogenic factors influence some or all components.

12.1.2.1 Inorganic Constituents

The most common inorganic cations in the soil solution (Table 12.1) usually are Ca^{2+}, Mg^{2+}, and K^+ (in that order) with a large number of minor cations, including various forms of Na^+, Fe^{2+}, Cu^{2+}, and Zn^{2+}. The most prevalent anions are HCO_3^-, Cl^-, and SO_4^{2-}. Soils that become flooded are strongly influenced by reducing conditions and microbial activities, and Fe^{2+}, HS^-, and SO_4^{2-} can take on greater importance. In contaminated environments, the entire composition of the soil solution will change to reflect the most soluble components of the contaminants.

The sum of soluble cations and anions usually is less than 10^{-2} mol L^{-1}. Among the cations, Ca^{2+} will comprise at least half of this total; for the anions, the division among HCO_3^-, Cl^-, and SO_4^{2-} will be dependent upon soil pH and composition of the soil solids. Naturally, saline soils (see Chapter 17 of *Handbook of Soil Sciences: Resource Management and Environmental Impacts*) will

contain elevated concentrations of Ca^{2+}, Mg^{2+}, Cl^-, SO_4^{2-}, and sometimes Na^+, depending upon pH and the source of the salts.

Concentrations of inorganic constituents in the soil solution are controlled by many factors, including pH, redox potential, and solid-phase composition. These considerations will be addressed later in this chapter and elsewhere in Chapters 15 through 18.

12.1.2.2 Organic Constituents

The composition of the soluble organic compounds in the soil solution is not as complex as that in the organic solid phase (see Chapter 11) but is a reflection of the organic components of the solid phase. Soluble organics also originate from the organisms in the soil including exudates from plant roots and soil microbes. Because these compounds are generated and degraded by microbial activity, the concentrations of these compounds in the soil solution can be more transient and more variable than soluble inorganic constituents.

As with soluble inorganic species, the organic constituents can be positively charged, negatively charged, or neutral. The chemical reactions of these compounds will be influenced by their electronic charge, but hydrophobic and hydrophilic tendencies are critical as well. For example, positively charged compounds that are water soluble can be adsorbed by cation exchange sites, negatively charged organics may form strong complexes with iron or aluminum oxides, and uncharged compounds may adsorb onto hydrophobic sites of soil minerals and organic matter.

The low-molecular-weight carboxylic acids typify soluble organics (Table 12.2). They are continually exuded by plant roots and soil microorganisms and are readily degraded with a half-life of hours. Carboxylic acids have the COOH functional group. The proton usually is dissociated in soil solutions, and the resulting negatively charged ligand often can act as a complexing agent for metals. Formic and tartaric acids are exuded by grass roots, acetic acid is generated under anaerobic conditions, oxalic acid is often associated with ectomycorrhizae, and citric acid is excreted by fungi and plant roots (Sposito, 2008). Typical concentrations for these acids range from 10^{-5} to 10^{-3} mol L^{-1}. Stevenson (1967) published an extensive review of these and other organic constituents in the soil solution.

TABLE 12.1 Inorganic Components Found in Soil Solutions

Category	Major Components (10^{-4}–10^{-2} mol L^{-1})	Minor Components (10^{-6}–10^{-4} mol L^{-1})	Others[a]
Cations	Ca^{2+}, Mg^{2+}, Na^+, K^+	Fe^{2+}, Mn^{2+}, Zn^{2+}, Cu^{2+}, NH_4^+, Al^{3+}	Cr^{3+}, Ni^{2+}, Cd^{2+}, Pb^{2+}
Anions	HCO_3^-, Cl^-, SO_4^{2-}	$H_2PO_4^-$, F^-, HS^-	CrO_4^{2-}, $HMoO_4^-$
Neutral	$Si(OH)_4^o$	$B(OH)_3^o$	

Concentration ranges are estimates and could change depending upon specific environments. The components listed are not necessarily the dominant solution species.

[a] Components normally found in concentrations <10^{-6} mol L^{-1} unless in a contaminated environment.

TABLE 12.2 Organic Components Found in Typical Soil Solutions

Category	Major Components (10^{-4}–10^{-2} mol L^{-1})	Minor Components (10^{-6}–10^{-4} mol L^{-1})
Naturally occurring	Formate, acetate, oxalate, amino acids, simple sugars	Citrate, phenolics, siderophores, proteins, alcohols, sulfhydryls
Anthropogenic	[a]	Herbicides, fungicides, insecticides, PCBs, petroleum hydrocarbons, surfactants, solvents, antibiotics, hormones

Concentration ranges are estimates and are subject to variability depending upon specific environmental conditions.

[a] Organic contaminants are present in low concentrations except in the case of spills, leaks, and accidental releases.

Organic pollutants include those compounds that have been introduced artificially into the soil, whether by design or accident. Most organic pesticides are applied at very low concentrations (0.1–10 kg ha^{-1}). Organics that have been spilled or accidentally leaked onto the soil can be present at many orders of magnitude higher. The resulting concentration in the soil solution will be dependent upon the total concentration in the soil, water solubility, strength of adsorption, volatility, and degradability of the compound in question. For example, the triazine herbicide, atrazine, normally is applied at a rate of approximately 2 kg ha^{-1}, has a water solubility of 35 mg L^{-1}, is weakly adsorbed by the soil, has a half-life of approximately 30 days, and has limited volatility. In contrast, glyphosate is applied at about the same rate as atrazine but is 1000 times more soluble, very strongly adsorbed, and not volatile. Immediately after application, atrazine concentrations in the soil solution can exceed 5 mg L^{-1} and represent an environmental threat to surface and groundwater. In contrast, aqueous glyphosate concentrations are nearly always <1 μg L^{-1}, and glyphosate is seldom detected in drinking water. (McBride, 1994, provides an excellent overview of the chemical behavior of pesticides in soil.) Organic solvents and petroleum hydrocarbons tend to have very low water solubilities (<1 μg L^{-1}), but their potential toxicity is high, and even trace concentrations in the soil solution may be environmentally significant.

12.2 Sampling the Soil Solution

The definition of the soil solution given in Section 12.1.1 is idealized and serves as a point from which the soil solution may be conceptualized. At the experimental level, the "soil solution" is defined by the method used to separate the aqueous phase from the rest of the soil. As discussed later, sampling methodology has a profound influence on the composition of the soluble constituents. Thus, consistent with the Heisenberg uncertainty principle for the study of subatomic particles, one cannot sample and examine the soil solution without altering it.

For both laboratory and field studies of the soil solution, one of the major problems associated with obtaining an unaltered soil solution is that the moisture content of field soils can rapidly change from air dry to saturated, and the moisture content influences the chemical and microbiological dynamics in the aqueous phase. Most techniques for obtaining samples of the soil solution function poorly when the moisture content is below saturation, and very few function at all moisture tensions of ≤33 kPa (1/3 bar). The choice of method and moisture content for obtaining a sample of the soil solution must be made to minimize the impact on solution composition while realizing that the act of sampling necessarily changes it.

An example of the influence of moisture content on soil chemical properties is the often-observed change in pH at different soil:solution ratios (Figure 12.1). Soil pH was measured for four soils with moisture contents ranging from 1:1 to a ratio of 10:1 water:soil (on a volume/mass basis). As the amount of
FIGURE 12.1 The impact of soil:solution ratio on the measured pH of two soils. Data for sandy loam and silty clay soils from Schwab (1992); surface horizon and waterlogged soil from Elberling and Matthiesen (2007). (Data from Schwab, A.P. 1992. Chemical and physical characterization of soils. *In* L.E. Erickson, S.C. Grant, and J.P. McDonald (eds.) Conf. Proc. Hazard. Subst. Res. University of Colorado, Boulder, Co., p. 326–344; Elberling, B., and H. Matthiesen. 2007. Methodologically controlled variations in laboratory and field pH measurements in waterlogged soils. Eur. J. Soil Sci. 58:207–214.)

water increased, the pH increased significantly. These observations lead to the following inescapable conclusion:

> Consideration of soil at field moisture contents is necessitated by the inability to predict consistently the effects of variation in soil to water ratios across broad ranges of soil solution composition; neither variation in total electrolyte concentrations or the activity ratios of specific ion components of the soil solution can be adequately resolved when water to soil ratios vary from field moisture contents to ratios >1. This is the main limitation to the use of water extracts as models of soil solution.

> **(Wolt, 1994)**

12.2.1 Laboratory Methods

Many laboratory methods have been developed for sampling the soil solution; only a few will be summarized here. The methods may be broadly categorized as aqueous extracts, column displacement, and pressure extraction. Each technique has advantages and limitations. (One must also consider proper sampling and handling techniques for the samples. For example, the simple act of air-drying the soil can have a profound effect on the soil chemical and microbiological properties [Bartlett and James, 1980; West et al., 1992].)

The steps to obtaining aqueous extracts include adding water to the soil to the point of saturation or beyond, equilibrating, and

removing solution. Equilibration times and separation techniques will depend upon the method used and desired application. If a saturated paste is prepared (United States Salinity Laboratory Staff, 1954) for the assessment of soil salinity, the paste is equilibrated for 16 h followed by vacuum removal of the soil solution. If equilibrium with soil solid phases is desired, equilibrations of hundreds to thousands of hours may be required (Kittrick, 1977; Schwab, 1989; Evans and Banwart, 2006; Sposito, 2008). The advantages of these techniques include ease of preparation, simple separation of soil and solution, and the ability to control many experimental parameters such as aeration and shaking. Limitations are unrealistic moisture contents, abrasion of soil surfaces during shaking, and uncertain impacts of wide soil:solution ratios on solution composition. This method has been applied with success in many instances (Lindsay, 1979; Berggren and Mulder, 1995).

Column displacement consists of forcing a fraction of the soil solution from the soil by leaching the soil with an aqueous solution (miscible displacement) or a water-insoluble organic solvent (immiscible displacement). These techniques have a long history, perhaps beginning with Thompson (1850) and Way (1850) leaching ammonium sulfate solutions through columns of soil and finding that the ammonium had been replaced by calcium. Schloesing (1866) used miscible displacement to obtain a sample of the soil solution; this method is quite similar to modern miscible displacement techniques (Adams, 1974). In all column displacement procedures, moist soil is packed into columns to a desired bulk density, sealing the surface by mechanically dispersing the clays, and leaching with the displacing liquid. The soil solution is collected in fractions until the displacing liquid appears in the leachate. This system may be modified to include pressure from the top (Ross and Bartlett, 1990) or vacuum applied to the bottom of the column (Wolt and Graveel, 1986).

The advantages of column displacement methods are obtaining soil solution from a soil at field moisture conditions, no requirement for grinding or shaking, and maintaining the dissolved gas content (except in the vacuum modification). Disadvantages include (1) generally short incubation times to prevent unusual microbial growth or changes in moisture content; (2) lack of knowledge of the fraction of the "true" soil solution that is obtained because of chemical and physical heterogeneity of the columns and because a large fraction of the water-filled pore space being occupied by the diffuse double layer; and (3) (in the case of immiscible displacement) an unknown influence of organic solvents on the displacement of ions.

Pressure extraction is the use of positive pressure, vacuum (negative pressure), or force applied by a centrifuge to remove the soil solution. For soils with moisture contents below saturation, the centrifuge method is more efficient than the positive pressure or vacuum methods. The efficiency of the latter two methods can be increased by employing a displacing solution, similar to some of the techniques described immediately above. Positive pressure methods generally refer to the use of a pressure membrane (Richards, 1941). A cylinder, equipped with small-pore filters on the inlet and outlet, is packed with the moist soil. Pressure of approximately 2 MPa (20 bar) is applied to the inlet, and the solution is collected

from the outlet. The centrifugation method, similarly, requires specialized equipment. The apparatus usually consists of a centrifuge tube to contain the moist soil; a permeable frit, filter, or ceramic beneath the soil; and a small volume at the bottom of the apparatus for collection of the extruded solution (Elkhatib et al., 1986). Large samples (up to 1 kg) usually are centrifuged at low speed, but smaller samples can be subjected to much greater speed and result in a greater fraction of the soil water being collected. An immiscible liquid also may be placed on the top of a small sample prior to centrifugation, a modification of immiscible displacement.

The pressure-membrane approach has not been used as widely as the centrifuge method because of lower yields, requirement for large samples, and specialty apparatus. The high-speed centrifuge method is an excellent choice because it uses equipment that is normally available in a soil chemistry laboratory, yields a sample very quickly (<1 h), and is amenable to a large number of samples. The disadvantages are similar to other displacement-type methods: short incubation times, an unknown fraction of the "true" soil solution that is sampled, uncertain impact of organic solvents (if used), and potential changes in the dissolved gas composition. The centrifugation method was used by van Hees et al. (2001) to infer the importance of organic matter and exchange reactions in the chemistry of Al in soils.

12.2.2 Field Methods

As is often the case in soil science, field methods of sampling the soil solution are more challenging than laboratory methods, particularly when one is interested in obtaining samples that are truly representative. Field methods cover a wide range of configurations: block or monolithic lysimeters; zero-tension or pan lysimeters; and porous-cup vacuum samplers.

Monolithic lysimeters are large blocks of soil (undisturbed or refilled) contained in a structure that has some means of collecting leachates. The apparatus are labor intensive and expensive to construct but are generally placed in a typical field setting to allow growth of vegetation while measuring a variety of soil parameters. The leachate collection system may be free drainage (i.e., zero-tension or air-entry potential) or use a vacuum system to impose a moderate moisture tension. Soil in contact with a free-drainage collection system must be very near saturation to allow water to move from the column to the collection area. The thickness of the near-saturated zone above the collection area will be dependent upon the texture of the soil, and the saturated condition will impact the chemistry, microbiology, and physics of the soil. Addition of a vacuum system, while adding to the complexity and cost of construction, will overcome the saturation problem. Unfortunately, the vacuum will at least partially "degas" the collected leachates.

Water flow through large lysimeters will affect directly the chemical composition of the leachates. In refilled versions, the original structure is destroyed, and, in the absence of plants, preferential flow within the soil is eliminated. However, this is unrepresentative of natural conditions. Block-type "undisturbed" lysimeters preserve much of the original soil structure, and water movement will be similar to the original field condition. In both block and refilled
FIGURE 12.2 A zero-tension, pan lysimeter in a typical field context. The collection vessel and drain tube are located in an excavated trench cut into the soil along the side of the sample area.

lysimeters, wall flow (movement of water in the spaces between the lysimeter walls and the soil) can be an important form of preferential transport of water and solutes (Till and McCabe, 1976). Wall flow can be minimized through careful design and construction, and its relative impact is lessened as the ratio of surface area of the side walls to the total volume of soil increases.

Zero-tension lysimeters include any device installed in the soil that collects water by free drainage of the soil above including pans, troughs, funnels, and plates. These lysimeters usually are installed from a trench. A slot is excavated from the trench into the soil that allows installation of the lysimeters (Figure 12.2). Leachate collects in the lysimeter, and the sample is removed by means of a hose or tube leading to the trench or to the soil surface. This lysimeter design is useful for monitoring the solutes that move with water. The assumption is made that the soil disturbance from digging the trench and installing the pan will have little impact on water flow and solute composition. However, water will not flow into the pan until the soil is nearly saturated. Water can accumulate above the interface between the soil and lysimeter and cause incoming water to move laterally away from the lysimeter. Modifications to this procedure such as putting the lysimeter under tension (Cole et al., 1961) can overcome this problem in part.

Porous-cup vacuum lysimeters (Figure 12.3) are widely used in sampling the soil solution. Their design is simple, and they are easily installed using standard soil sampling equipment. Entire assemblies are readily built or available commercially. A length of PVC pipe is fitted with and glued to a ceramic cup. A rubber stopper with two air lines is placed in the opposite end of the pipe. The lysimeter is buried in the soil with the ceramic cup facing down and the air lines extending to the soil surface. One air line is used for drawing a vacuum, either with a hand pump or with a portable electric pump. The lines are sealed, and the lysimeter is allowed to draw the soil solution into the ceramic
FIGURE 12.3 Design of a typical porous-cup vacuum lysimeter.

cup. (A continuous vacuum may be applied, or the vacuum may be applied intermittently.) The second air line extends to the bottom of the cup and is used for retrieving the collected sample either by drawing a vacuum on the retrieval line (marked B in Figure 12.3) or by applying pressure on the other line (A).

Porous-cup lysimeters have been criticized as field samplers of the soil solution (Caron et al., 1999). The ceramic cup has the potential to retain analytes or to contaminate the sample (Wood, 1973), particularly for inorganic species. Likewise, the PVC tube can retain organic compounds of interest. The area of soil that is sampled is not known (Warrick and Amoozegar, 1977), but will be influenced by the vacuum applied (Morrison and Lowry, 1990), the texture of the soil, the method of installation, and soil moisture content. Unlike the other field methods described above, vacuum pore water samplers will operate only when the operator engages them. Unless the porous cup is in saturated soil, the soil solution will not flow into it until vacuum is applied.

Each field method has positive and negative aspects. The monolithic lysimeters are, in essence, a field laboratory with all parameters either controllable or measurable. However, they are difficult and expensive to construct and maintain, and wall effects can be dominant. Zero-tension lysimeters are less expensive but require significant disturbance to the soil adjacent to the site, and water flow patterns may be altered immediately above the interface between soil and lysimeter. Vacuum pore water samplers are the least expensive of all field methods but collect the smallest fraction of the soil solution. In all cases, the soil solution will be defined by the specifics of the method used.

12.3 Thermodynamics of the Soil Solution

In discussing the thermodynamics of aqueous systems, strong distinctions are made between chemical equilibrium and nonequilibrium (kinetic) systems. Overlap exists between the statics and dynamics of solutions both on theoretical and

practical basis. In this section, only equilibrium thermodynamics will be addressed. Kinetics are addressed in Chapter 13. The assumption of equilibrium may be applied safely to only a fraction of the reactions occurring in soils; many reactions do not achieve equilibrium before new perturbations are imposed. Despite serious practical limitations, equilibrium models are important because "they are simpler in that they require less information, but they are nevertheless powerful when applied within their proper limits" (Stumm and Morgan, 1996).

Soil solutions are open systems in which energy and matter are exchanged readily with the surrounding environment. Experimentalists often are more familiar with closed systems in which such exchanges do not occur and rigorous mass and energy balances can be applied. Thus, the study of soils in natural settings can require some adjustments in design, execution, and interpretation. Open systems will be assumed in all derivations discussed later unless otherwise noted.

Chemical thermodynamics of aqueous solutions have been developed to various degrees of depth and detail, depending upon the application. Stumm and Morgan (1996) provide an excellent, in-depth discussion of equilibrium thermodynamics for aqueous systems. Wolt (1994) provided a discussion of similar depth but with the ultimate application to soil solutions. Sposito (1981) dedicated an entire textbook to the subject of the thermodynamics of soil solutions. The reader is referred to these references for a thorough discussion of chemical thermodynamics applied to aqueous solutions. In this chapter, important thermodynamic laws and equations will be stated and discussed; they will not be derived.

12.3.1 Fundamentals, Units, and Variables

As mentioned previously, true equilibrium is achieved in only a fraction of the reactions that occur in soil solutions but is a powerful tool when properly applied. Some of the reasons for investigating the application of equilibrium thermodynamics to systems that are frequently not in equilibrium include determining whether some or all of the components of the solution are in equilibrium; comparing the measured system with systems in equilibrium; quantifying the energy of disequilibrium (i.e., the energy input necessary to achieve equilibrium); and calculating the effects of temperature on equilibria. The equations necessary to obtain these goals are presented in the following sections.

TABLE 12.3 Variables, Thermodynamic Functions, and Equations of State

Variable	Units	Function	Equation of State
Temperature (T)	K	Enthalpy (H)	$dH = T\,dS + V\,dP$
Entropy (S)	J deg^{-1}	Helmholtz free energy (A)	$dA = -S\,dT - P\,dV$
Pressure (P)	kPa	Gibbs free energy (G)	$dG = -S\,dT + V\,dP$
Volume (V)	L	Internal energy (E)	$dE = T\,dS - P\,dV$
Chemical potential	J mol^{-1}		
Quantity	mol		

Important variables and functions and associated units are given in Table 12.3. Nearly all thermodynamic equations relative to soil solutions are derived from the four principles of thermodynamics and the first and second laws of thermodynamics (Stumm and Morgan, 1996). The four principles of thermodynamics establish an absolute temperature scale, define the internal energy of a system, and describe the relationship between entropy and temperature.

12.3.2 First and Second Laws of Thermodynamics

The first law of thermodynamics for equilibrium systems of fixed compositions,

$$dE = dq - dw, \tag{12.1}$$

represents the changes in internal energy (E) as affected by heat transferred to the system (q) and work done by the system (w). For a reversible process, the second law is given by

$$dS_{sys} = \frac{dq}{T} \tag{12.2}$$

and relates the temperature and heat transferred to a system with entropy (S). Other forms of this equation exist for the system plus its surroundings as well as irreversible changes in a system.

From the basic (not differentiated) equations $H = E + PV$ and $G = E + PV - TS$, one can obtain the important relationship, $G = H - TS$, where G is the Gibbs free energy, H is enthalpy, P is pressure, and V is volume. For a finite state change at constant pressure and temperature,

$$\Delta G = \Delta H - T\Delta S. \tag{12.3}$$

This equation, a restatement of the second law of thermodynamics in terms of state functions of the system, is used in the application of thermodynamics to numerical solutions of chemical problems.

12.3.3 Associated Thermodynamic Relationships

The development of theoretical thermodynamics can be quite detailed, but its utility can be realized only if expressed in measurable variables. For example, enthalpy change (dH) in Table 12.3 can be described as $dH = dq + V\,dP$; if $dP = 0$ (constant pressure process), then $dH = dq_P$. This expression is particularly useful in determining temperature effects because constant pressure heat capacity (C_P) is measurable and is given by

$$C_P = \left(\frac{dq}{dT}\right)_P. \tag{12.4}$$

In the absence of external work, $q_P = \Delta H$.

Under conditions of constant pressure and constant temperature the state of a system is characterized by dG. For irreversible changes in a system,

$$dG - V\,dP + S\,dT < 0, \tag{12.5}$$

and for reversible changes,

$$dG - V\,dP + S\,dT = 0. \tag{12.6}$$

The above equations are applicable only for systems of constant chemical composition, $dn_i = 0$. When the composition of only species i is allowed to change,

$$dG = \left(\frac{\partial G}{\partial T}\right)_{P,n_j} dT + \left(\frac{\partial G}{\partial P}\right)_{T,n_j} dP + \sum_i \left(\frac{\partial G}{\partial n_i}\right)_{P,T,n_j} dn_i. \tag{12.7}$$

12.3.4 Chemical Potential and Free Energy

The chemical potential, μ, of a species i is defined as

$$\mu_i = \left(\frac{\partial G}{\partial n_i}\right)_{P,T,n_j}. \tag{12.8}$$

Employing the relationships $(\partial G/\partial T)_{P,nj} = -S$ and $(\partial G/\partial P)_{T,nj} = V$ yields the equation

$$dG = -S\,dT + V\,dP + \sum \mu_i\,dn_i, \tag{12.9}$$

and for a single-phase system at constant temperature and pressure,

$$dG = \sum \mu_i\,dn_i. \tag{12.10}$$

For a multiphase system, dG for the entire system is obtained by summing $\mu_i\,dn_i$ over all phases. When equilibrium is established for all reactions and phases, $dG = 0$.

These basic equations can be manipulated further to yield equations for chemical potentials of components in various phases.

The resulting relationships depend upon assumptions made during the derivation. Equations for gases and electrolytes are summarized in Table 12.4. As an example derivation for an ideal gas, consider the partial free energy of this gas with respect to P at constant T and n:

$$\left(\frac{\partial G}{\partial P}\right)_{T,n} = V \tag{12.11}$$

and, thus,

$$\left(\frac{\partial G}{\partial P}\right)_{T,n} = \frac{nRT}{P}. \tag{12.12}$$

If the second equation is rearranged and integrated from G^o (standard free energy) to G and from P^o (standard pressure) to P, the result is

$$G - G^o = nRT\ln\left(\frac{P}{P^o}\right). \tag{12.13}$$

Differentiation with respect to n and recalling the definition for chemical potential gives

$$\mu_i = \mu_i^o + RT\ln\left(\frac{P_i}{P^o}\right), \tag{12.14}$$

where μ_i^o is the chemical potential for the ideal gas in its standard state (e.g., as defined by the conditions given in Table 12.4) at $T = 298.15\,K$ and $P = 101.33\,kPa$ (1 atm). Similar derivations for real gases, condensed phases that obey Raoult's law and condensed phases that obey Henry's law, are summarized by Wolt (1994).

Sposito (1994) discussed the standard states for phases and elements relevant to the study of soil solutions.

TABLE 12.4 Expressions for the Chemical Potential of Components in Gas and Condensed Phases as Influenced by the Assumptions of the Behavior of the Component

Phase	Chemical Potential	Coefficients	Standard State
Ideal gas	$\mu_i = \mu_i^o + RT\ln(P_i/P^o)$		298.15 K, 101.33 kPa; pure ideal gas at 101.33 kPa
Nonideal gas	$\mu_i = \mu_i^o + RT\ln(P_i\lambda_i)$	$\lambda_i \equiv$ fugacity coefficient	298.15 K, 101.33 kPa; pure nonideal gas at 101.33 kPa, $\lambda_i = 1$
Condensed phase: follows Henry's law	$\mu_i = \mu_i^o + RT\ln(C_i)$	$C_i \equiv P_i/K_{Hi}$	Pure condensed phase component, $C_i^o = 1$
Condensed phase: does not follow Henry's law	$\mu_i = \mu_i^o + RT\ln(C_i\lambda_i)$	$\lambda_i \equiv$ Henry's law coefficient	Pure condensed phase component, $C_i^o = 1$ and $\lambda_i = 1$
Condensed phase: follows Raoult's law	$\mu_i = \mu_i^o + RT\ln(\chi_i)$	$\chi_i = P_i/P^o$	Pure condensed phase component, $\chi_i^o = 1$
Condensed phase: does not follow Raoult's law	$\mu_i = \mu_i^o + RT\ln(\chi_i\lambda_i)$	$\lambda_i \equiv$ Raoult's law coefficient	Pure condensed phase component, $\chi_i^o = 1$ and $\lambda_i = 1$
Solute in ideal, dilute solution	$\mu_i = \mu_i^o + RT\ln(C_i)$		Pure condensed phase component, $C_i^o = 1$
Solute in nonideal solution	$\mu_i = \mu_i^o + \mu RT\ln(C_i\gamma_i)$	$\gamma_i \equiv$ single ion activity coefficient	Pure condensed phase component, $C_i^o = 1$ and $\gamma_i = 1$
Solute in nonideal solution	$\mu_i = \mu_{\pm}^o + \nu RT\ln(C_{\pm}\gamma_{\pm})$	$\gamma_{\pm} \equiv$ mean activity coefficient $\nu =$ stoichiometric coefficient	Pure condensed phase component, $C_{\pm} = 1$ and $\gamma_{\pm} = 1$

12.3.5 Chemical Potential and Activities in Ideal Solutions

Perhaps the most important expressions for chemical potential in dealing with soil solutions are those for solutions of electrolytes. A classical case is that of NaCl dissolved in water. Sodium chloride is a strong electrolyte, indicating that it is dissociated fully with no NaCl complexes in the aqueous solution. The chemical potential of this solution is the sum of the chemical potentials for the Cl^- and Na^+ species:

$$\mu_{NaCl} = \mu_{Na^+} + \mu_{Cl^-}. \tag{12.15}$$

In an ideal, dilute solution, the equations for the chemical potentials of the individual ions with concentrations C_{Na^+} and C_{Cl^-} would be

$$\mu_{Na^+} = \mu_{Na^+}^o + RT \ln(C_{Na^+}), \tag{12.16}$$

$$\mu_{Cl^-} = \mu_{Cl^-}^o + RT \ln(C_{Cl^-}). \tag{12.17}$$

The standard potential for an aqueous solution of NaCl ($\mu_{NaCl(aq)}^o$) is defined as

$$\mu_{NaCl(aq)}^o \equiv \mu_{Na^+}^o + \mu_{Cl^-}^o, \tag{12.18}$$

and the total chemical potential is

$$\mu_{NaCl(aq)} = \mu_{NaCl(aq)}^o + RT \ln(C_{Na^+} C_{Cl^-}). \tag{12.19}$$

If the concentration of the salt is defined as C_{NaCl} and realizing that $C_{NaCl} = C_{Na^+} = C_{Cl^-}$, then

$$\mu_{NaCl} = \mu_{NaCl}^o + RT \ln(C_{NaCl})^2. \tag{12.20}$$

12.3.6 Activities and Activity Coefficients: Nonideal Solutions

For nonideal solutions, the concept of activity and activity coefficient is introduced. A nonideal solution of NaCl would have a chemical potential of

$$\mu_{NaCl(eq)} = \mu_{NaCl(aq)}^o + RT \ln(a_{Cl^-} a_{Na^+}) \tag{12.21}$$

or

$$\mu_{NaCl(eq)} = \mu_{NaCl(aq)}^o + RT \ln(C_{Cl^-} \gamma_{Cl^-} C_{Na} + \gamma_{Na^+}), \tag{12.22}$$

in which a_i is the activity of component I and γ_I is the activity coefficient of component i. The product $a_{Na^+} a_{Cl^-}$ is designated by a_{NaCl}, which is the activity of the aqueous solute, and its mean activity is $a_\pm = (a_{Na^+} a_{Cl^-})^{1/2}$, which can be determined experimentally. Similarly, the mean activity coefficient, $\gamma_\pm$, is equal to $(\gamma_{Na^+} \gamma_{Cl^-})^{1/2}$; $\gamma_{Na^+} \gamma_{Cl^-}$ can be determined experimentally by measuring water vapor pressures over NaCl solutions of varying concentrations.

12.3.7 Equilibrium Constants

The Gibbs free energy of a reaction can be related to the system composition through the expressions for chemical potential:

$$\mu_I = \mu_i^o + RT \ln a_i \tag{12.23}$$

and ΔG

$$\Delta G = \sum_i \upsilon_i \mu_i, \tag{12.24}$$

in which υ_i is the stoichiometric coefficient of a component i in the reaction. Combining these equations gives

$$\Delta G = \sum_i \upsilon_i \mu_i^o + RT \sum_i \upsilon_i \ln(a_i) \tag{12.25}$$

or

$$\Delta G = \Delta G^o + RT \ln \prod_i (a_i)^{u_i}, \tag{12.26}$$

where

$$\Delta G^o = \sum_i \upsilon_i \mu_i^o, \tag{12.27}$$

ΔG^o is the standard Gibbs free energy change of the reaction
Π_i is the quotient of concentrations of products over reactants

Consider the reaction,

$$aA + bB \leftrightarrow cC + dD, \tag{12.28}$$
in which
  a and b are the stoichiometric coefficients of reactants A and B
  c and d are the stoichiometric coefficients of products C and D

The expression for Π_i would be

$$\left[\frac{a_C^c a_D^d}{a_A^a a_B^b} \right].$$

The expression often is given the symbol Q. Thus,

$$\Delta G = \Delta G^o + RT \ln Q. \tag{12.29}$$

At equilibrium, $\Delta G = 0$, $Q = K$ (the equilibrium constant), and

$$\Delta G^o = -RT \ln K. \tag{12.30}$$

Both K and Q are written in terms of activities (a_i), but activities of individual species are not measurable. However, both can be written in terms of concentrations using the relationship between activity and concentration, $a_i = C_i \gamma_1$:

$$K = \frac{a_C^c a_D^d}{a_A^a a_B^b} = \frac{(C_C \gamma_C)^c (C_D \gamma_D)^d}{(C_A \gamma_A)^a (C_B \gamma_B)^b}. \tag{12.31}$$

12.3.8 Effects of Temperature and Pressure

The general expression for the effect of temperature on the free energy of reaction is

$$\left(\frac{\partial \Delta G^o / T}{\partial T} \right)_P = -\frac{\Delta H^o}{T^2}, \tag{12.32}$$

and the van't Hoff equation for the corresponding equilibrium constant is

$$\frac{d \ln K}{dT} = \frac{\Delta H^o}{RT^2}. \tag{12.33}$$

The temperature dependence of enthalpy of reaction is

$$H_2 - H_1 = \int_{T_1}^{T_2} C_p \, dT. \tag{12.34}$$

If ΔH^o is independent of temperature,

$$\ln \frac{K_2}{K_1} = \frac{\Delta H^o}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) \tag{12.35}$$

or, when the heat capacity ($\Box C_p^o$) is independent of temperature,

$$\ln \frac{K_2}{K_1} = \frac{\Delta H^o}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right) + \frac{\Delta C_P^o}{R} \left(\frac{T_1}{T_2} - 1 - \ln \frac{T_1}{T_2} \right) \tag{12.36}$$

or

$$\ln K = B - \left(\frac{\Delta H_o}{RT} \right) + \frac{\Delta C_P^o}{R} \ln T, \tag{12.37}$$

where B and ΔH_o are constants (Stumm and Morgan, 1996). When $\Box C_p^o$ is a function of temperature, the form of the final equation will reflect the temperature-dependent expression for the heat capacity.

The effects of pressure on free energy and equilibrium constants are handled in a fashion similar to temperature (Stumm

and Morgan, 1996). The general expression, when ΔV^o is independent of pressure,

$$\left(\ln \frac{K_P}{K_1} \right)_P = -\frac{\Delta V^o (P - 1)}{RT}. \tag{12.38}$$

With specific reference to aqueous solutions,

$$\mu_i = \mu_i^o + RT \ln \gamma_i C, \tag{12.39}$$

$$\left(\frac{\partial \ln K}{\partial P} \right)_{T,C} = -\frac{\Delta V^o}{RT}, \tag{12.40}$$

$$\left(\frac{\partial \ln \gamma_i}{\partial P} \right)_{T,C} = -\frac{\overline{V}_i - \overline{V}_i^o}{RT}, \tag{12.41}$$

where

$\overline{V}_i$ is the partial molar volume
$\overline{V}_i^o$ is the standard partial molar volume of species i

12.3.9 Single-Ion Activity Coefficients

The mean activity coefficient of a salt in solution, $\gamma_\pm$, is measurable by experimental methods. However, the activity coefficient of a single ion, such as γ_{Na^+} or γ_{Cl^-}, is not measurable and must be estimated by theoretical models. Such a model was provided by the Debye–Huckel theory, which combined thermodynamic and electrostatic expressions to describe the interaction between charged species in solution. In its first configuration, the theory was based upon the assumption that the ions act as point charges. The resulting equation, the Debye–Huckel limiting law, was

$$\log \gamma_i = -AZ_i^2 (I^{0.5}), \tag{12.42}$$

where

Z_i is the valence of the ion
I is the ionic strength of the solution $\left(I = 0.5 \sum C_i Z_i^2 \right)$
A is related to the dielectric constant for water and has a value of 0.509 at 298.15 K and 101.33 kPa

Activity coefficients calculated from this equation begin to deviate from measurements when $I > 0.005 \, \text{mol L}^{-1}$. The Debye–Huckel theory was extended to greater ionic strengths ($I = 0.1 \, \text{mol L}^{-1}$) by adding terms that account for the spatial interaction of the ions:

$$\log \gamma_i = \frac{-AZ_i^2 I^{0.5}}{1 + \beta a_i^o I^{0.5}}, \tag{12.43}$$

in which β is a constant that depends upon the nature of the solvent and temperature. For water, β is equal to 0.328×10^8 at 298.15 K and 101.33 kPa. The ion size parameter, a_i^o, ranges from

(2.5 to 9) × 10⁻⁸ and must be obtained from a compilation of values (Kielland, 1937). The Davies equation is a further modification of the Debye–Huckel and is applicable when $I < 0.5\,\mathrm{mol\,L^{-1}}$:

$$\log \gamma_i = -AZ_i^2 \left(\frac{I^{0.5}}{1 + I^{0.5}} - 0.3I \right). \tag{12.44}$$

The advantages of the Davies over other equations are the applicability to higher ionic strengths and the elimination of the necessity of using β values.

12.3.10 Electrochemical Potential

The standard electrochemical potential of a oxidation/reduction reaction, E^o, is the potential of the reaction relative to the oxidation of $H_2(g)$ to H^+ in aqueous solution. The balanced chemical reaction of such a cell involving the reduction of Cu^{2+} to the metal would be

$$Cu^{2+}(aq) + H_2(g) \leftrightarrow 2H^+ + Cu(s). \tag{12.45}$$
The half-cell reactions are conveniently written as follows, with the implicit understanding that the hydrogen half-cell is always present:

$$Cu^{2+}(aq) + 2e^- \leftrightarrow Cu(s). \tag{12.46}$$
For any given reaction, the Nernst equation may be derived:

$$E_H = E_H^o + \frac{2.303RT}{nF}\log \frac{\prod_i \{ox\}^{n_i}}{\prod_j \{red\}^{n_j}}, \tag{12.47}$$

where
  E_H is the measured potential
  E_H^o is the standard potential of the cell
  R is the gas constant
  T is temperature in degrees K
  n is the number of electrons involved in the reaction
  F is the Faraday constant
  Π designates the product of either the reactants or products in the equation

For any oxidation/reduction reaction, the relationship between the electrode potential and pe, negative logarithm of the electron activity, $-\log(e^-)$, may be derived as

$$pe = \frac{F}{2.303RT}E_H, \tag{12.48}$$

or $pe = E_H/59.2$ when E_H is in mV and determined at 298.15 K. As with H^+, aqueous solutions do not contain free electrons, and the concentration of solvated electrons is vanishingly small. Nevertheless, pe is a very convenient parameter in manipulating equilibrium equations and plotting data.
FIGURE 12.4 Relationship between crystallographic radius and enthalpy of hydration of monovalent, divalent, and trivalent cations and monovalent halide anions. The drawn lines represent linear regressions: $R^2 = 0.98$ for monovalent cations; $R^2 = 0.90$ for divalent cations; $R^2 = 0.99$ for trivalent cations; and $R^2 = 0.98$ for monovalent anions. (Data from Bohn, H., B. McNeal, and G. O'Connor. 1985. Soil chemistry. Wiley Interscience, New York; Morris, D.F.C. 1969. Ionic radii and enthalpy of hydration of ions. Struct. Bond. 63:157–159.)

12.3.11 Heat of Hydration of Ions

One of the most important reactions for ions in solution is hydration, the electrostatic interaction between the polar water molecules and the charged ion. When an ion is released into aqueous solution, heat is released as water molecules form a somewhat ordered structure around the ion. The water that surrounds the ion tends to insulate the charged species from other ions in solution. In infinitely dilute solutions, this solvation effect completely isolates the ions from interacting with each other.

The heat released during solvation of an ion by water is the heat of hydration, $\Delta H_{\text{hydration}}$. The strength of the water–ion interaction increases with increasing valence because higher charged ions have the capacity to react with more water molecules. Within a group of ions of the same valence, $\Delta H_{\text{hydration}}$ decreases (becomes more negative) linearly with decreasing crystallographic radius (Figure 12.4). Thus, a small monovalent ion such as Li^+ releases more heat upon hydration than the much larger Cs^+ ion. A direct result of this is that Li^+ also has a greater hydrated radius than Cs^+, which is partly responsible for some of the differences in strength of retention of these ions by cation exchange sites in soil (see Chapter 17).

12.4 Interactions of Gases with the Soil Solution

Chemical reactions between gases and the liquid aqueous phase are important not only in the soil solution but also in biological systems, surface water, groundwater, and the atmosphere.

For example, acid rain is a long-recognized problem that results from the combustion of fossil fuels. The oxidation of C, S, and N in the fuels generates several gaseous oxides including CO_2, NO_2, NO, SO_2, and SO_3. When these oxides dissolve in water, they generate acids: H_2CO_3, HNO_3, HNO_2, H_2SO_3, and H_2SO_4. The extent to which the gaseous oxides dissolve in the water can be described by Henry's law referenced in Section 12.3.4 and given in Table 12.4.

12.4.1 Henry's Law

The equilibrium distribution of a species between the gas phase and the aqueous is given by Henry's law. The expression is based upon the thermodynamic parameter, chemical potential, and requires the determination of a partitioning coefficient for each gas. The thermodynamic expression is

$$f_A = K a_A, \qquad (12.49)$$

where

　K is a constant
　f_A is the fugacity of the gas
　a_A is the activity of the species in the aqueous phase

The transition between the above thermodynamic equation and a usable expression with measurable terms is made simpler if one first assumes the condition of dilute solutions and low concentrations in the gas phase. Under these circumstances, Henry's law may be written in one of two ways, either of which is correct. In the first expression, the partitioning coefficient (H) is dimensionless:

$$\frac{\left[A(\text{aq})\right]}{\left[A(\text{g})\right]} = H. \qquad (12.50)$$

The units of concentration for the gaseous and aqueous species must be the same (e.g., mol L^{-1}). In the second form of Henry's law, the partitioning coefficient is not dimensionless:

$$\frac{\left[A(\text{aq})\right]}{P_A} = K_H. \qquad (12.51)$$

If the units of concentration for the aqueous component are mol L^{-1} and the partial pressure is in atmospheres, then K_H must have units of mol L^{-1} atm^{-1}. The conversion between H and K_H is

$$K_H = \frac{H}{RT}. \qquad (12.52)$$

Table 12.5 contains a compilation of K_H values for important gases in soils and other settings.

　Although Henry's law dictates that the solubility of gases in water is a linear function only of their partial pressures, many of the dissolved species react further with water to form acids that are subject to deprotonation. Thus, pH is an important

TABLE 12.5 Henry's Law Constants (K_H) for Important Gas–Water Reactions

Gas	$K_{H,298.15K}$ (mol L^{-1} atm^{-1})	Gas	$K_{H,298.15K}$ (mol L^{-1} atm^{-1})
H_2	7.78×10^{-4}	O_2	1.27×10^{-3}
N_2	6.53×10^{-4}	N_2O	2.42×10^{-2}
NO	1.92×10^{-3}	CO	9.77×10^{-4}
CO_2	3.39×10^{-2}	H_2S	1.02×10^{-1}
SO_2	1.36	Cl_2	9.31×10^{-2}
CH_4	1.41×10^{-3}	NH_3	5.71×10^{1}
O_3	1.04×10^{-4}		

　Constants were calculated from the data of Gevantman (2001) with the exception of NH_3 (Sposito, 2008).

controlling variable for the total dissolved component in aqueous solution. Calculations also can be complicated by whether the system contains an infinite sink of the gas (open system) or if the gas is limited (closed system). These calculations are handled in detail by Stumm and Morgan (1996).

12.4.2 Volatile Organic Compounds

Many organic compounds are subject to loss from solid, liquid, or aqueous phases through volatilization. As with inorganic gases, the tendency for volatile organic compounds to partition between the aqueous phase and the atmosphere can be described by Henry's law. Henry's law constants can be calculated by measuring aqueous and gaseous phase concentrations in systems at equilibrium (Table 12.6).

12.4.3 Rates of Dissolution of Gases in Water

Quantification of equilibrium distributions of volatile compounds between the atmosphere and aqueous phase is more powerful when accompanied by an understanding of the rates of reactions. Transfer of a gas across the liquid/gas interface can be approximated by a diffusion model with two diffusion films

TABLE 12.6 Water Solubilities, Vapor Pressures, and Henry's Law Constants for Selected Organic Compounds

Compound	Water Solubility (mol L^{-1})	Vapor Pressure, P_A (atm)	K_H (mol L^{-1} atm^{-1})
Hexane	7.0×10^{-4}	0.25	2.8×10^{-3}
n-Octane	5.8×10^{-6}	1.8×10^{-2}	3.1×10^{-4}
Dieldrin	5.8×10^{-7}	6.6×10^{-9}	88
Lindane	2.6×10^{-5}	8.3×10^{-8}	313
Naphthalene	2.6×10^{-4}	1.0×10^{-4}	2.6
Benzene	2.3×10^{-2}	0.12	0.19
Toluene	5.6×10^{-3}	3.7×10^{-2}	0.15
Biphenyl	4.9×10^{-5}	7.5×10^{-5}	0.65
Dimethyl sulfide	0.35	0.63	0.56

　Source: Stumm, W., and J.J. Morgan. 1996. Aquatic chemistry. Chemical equilibria and rates in natural waters. Wiley Interscience, New York.

　A more comprehensive compilation is available in Staudinger and Roberts (1996).

(liquid phase and gas phase) assuming that the bulk phases are well mixed (Stumm and Morgan, 1996). The diffusion films are assumed to be within a very small distance of the interface.

The flux across the films of thickness z is expressed by Fick's law:

$$F = -D\frac{dc}{dz}. \tag{12.53}$$

The units for flux, F, will depend upon the units of concentration (c), diffusion coefficient (D), and thickness; assuming concentrations in mol m^{-3}, D in m^2 s^{-1}, and distance in m, then F will have units of mol m^{-2} s^{-1}. A steady state will have been achieved when the flux across the two films is equal. The thickness of the air diffusion film is assumed to be z_{air}; the thickness of water diffusion film is z_{water}; the concentrations in the air and water are c_{air} and c_{water}; the concentrations in the air–water interface is c_{a-w}; and the concentration in the water–air interface is c_{w-a}. Therefore, at steady state,

$$F = -\frac{D_w}{z_w}(c_{w-a} - c_w) = -\frac{D_a}{z_a}(c_a - c_{a-w}). \tag{12.54}$$

Assuming that the transfer across the interfaces is much faster than any ensuing chemical reactions that may occur, Henry's law may be applied to the concentrations in the interface regions (using the dimensionless constant from Section 12.4.1):

$$H = \frac{c_{w-a}}{c_{a-w}} = K_H RT. \tag{12.55}$$

Substituting into the steady-state equation,

$$F = \frac{D_a}{z_a}\left(\frac{c_{w-a}}{H} - c_a\right) = \frac{D_w}{z_w}(c_w - c_{w-a}). \tag{12.56}$$

Using data from Lovelock et al. (1993 in Stumm and Morgan, 1996), one can calculate that the flux of freon across the water–gas interface in marine environments is 1.5×10^{-9} g cm^{-2} year^{-1}. Extended derivations and similar calculations can be made for other chemical systems after making allowances for chemical reactions. For example, the steady-state flux of $CO_2(g)$ from a lake into the atmosphere is 6×10^{-9} mol cm^{-2} s^{-1} at pH 6.7, total alkalinity of 3×10^{-3} mol L^{-1}, and 298.15 K.

12.5 Acid–Base Reactions in the Soil Solution

Acid and base reactions are the most fundamental and often the most important in soil solutions. The weathering of primary minerals often generates alkaline conditions, and natural and anthropogenic activities can generate acidic conditions. The rates and extents of many chemical reactions are dependent upon soil solution pH including biological activity, mineral

dissolution, partitioning of some gases, and bioavailability of critical nutrient elements. This section will address some of the important acid–base concepts and discuss the numerical handling of related equilibria.

12.5.1 Fundamentals of Acid–Base Chemistry in Soil Solution

The central component of acid–base reactions is the proton or hydrogen ion, H$^+$. This ion does not actually exist as H$^+$ in aqueous solutions but is hydrated to form H_3O^+, $H_7O_3^+$, $H_9O_4^+$, etc. For the sake of simplicity in representing the equilibria involving the proton, the symbol H$^+$ will be used.

According to the Bronsted–Lowry concept, an acid is any substance that donates a proton to another substance. Similarly, a Bronsted–Lowry base is any substance that accepts a proton from another substance. Using this definition, hundreds of reactions in soil solutions are examples of acids and bases. For example, bicarbonate ion dissociates readily to form carbonate and H$^+$:

$$HCO_3^- \leftrightarrow CO_3^{2-} + H^+. \tag{12.57}$$
In this case, bicarbonate is acting as an acid. Bicarbonate may also act as a base, accepting a proton to form carbonic acid:

$$HCO_3^- + H^+ \leftrightarrow H_2CO_3^o. \tag{12.58}$$

Although the discussions of Bronsted–Lowry theory for acids and bases presented here will be limited to aqueous systems, the theory is applicable to all solvents in which protons may be exchanged, including ammonia, sulfuric acid, and ethanol.

Metal ions in aqueous solutions are readily solvated and, as such, exist as hydrates rather than bare ions. The number of water molecules surrounding a cation in the first hydration layer will be dependent upon the ionic radius of the cation and its charge. The water in the hydration sphere tends to act as a weak acid, donating a proton to the solution and (in essence) contributing a hydroxyl ion to the metal:

$$\left[Fe(H_2O)_6\right]^{3+} \leftrightarrow \left[Fe(H_2O)_5OH\right]^{2} + H^+. \tag{12.59}$$
The acidity of the water associated with the hydrolysis reaction increases with increasing valence and decreasing ionic radius of the central cation.

Another acid–base concept was formulated by G.N. Lewis (Lewis and Randall, 1923). A Lewis acid accepts a pair of electrons from a Lewis base. All Bronsted–Lowry acids and bases are also Lewis acids and bases, but the Lewis definition encompasses more reactions. In the neutralization reaction of H$^+$ with OH$^-$ to give water, a lone pair of electrons on the hydroxyl is donated to hydrogen; thus, this reaction fits both acid and base definitions. When an orthophosphate ion reacts with Fe(III) in the structure of goethite, the Fe(III) accepts an electron pair from the oxygen

on the phosphate group to form the bond. This fits the Lewis definition of an acid–base reaction but is clearly not a Bronsted–Lowry acid–base pair.

12.5.2 Calculations for Acid–Base Equilibria

Graphical representations of acid–base equilibria can take several forms, but the underlying calculations are built on the same theoretical foundation. Whether the system is simple or complex, the approach is the same, although organizing and executing the computations can be challenging for large systems. The first step is to identify the participating components, assemble the pertinent equations, identify the master variables, and solve the equations in terms of the master variables. A simple system, aqueous solution of carbonate, will be used as an example with more complex systems developed later in this chapter.

In this system, the species in solution would be OH^-, H^+, $H_2CO_3^o$, HCO_3^-, and CO_3^{2-} with $CO_2(g)$ in the gas phase. The defining reactions and equilibrium constants are given in Table 12.7. The equilibrium constants (K^o) are given at zero ionic strength, 298.15 K, and 101.33 kPa (1 atm) and are taken from Lindsay (1979). By defining the equilibrium constants at zero ionic strength, it is assumed that all species are given in terms of activities. In Figure 12.5, activities of the three solution species in equilibrium with 0.0003 atm $CO_2(g)$ are plotted as a function of pH. The predominant solution species below pH 6.33 is $H_2CO_3^o$ at an activity of $10^{-4.98}$. Between pH 6.33

TABLE 12.7   Controlling Equations for Equilibria Involving $CO_2(g)$ and $H_2O(l)$

Equation	$\log K^o$
$CO_2(g) + H_2O(l) \leftrightarrow H_2CO_3^o$ (aq)	−1.46
$H_2CO_3^o \leftrightarrow HCO_3^- + H^+$	−6.36
$H_2CO_3^o \leftrightarrow CO_3^{2-} + 2H^+$	−16.69

Source: Lindsay, W.L., *Chemical Equilibria in Soils*, Wiley Interscience, New York, 1979.
FIGURE 12.5 Activities of carbonate species as affected by pH assuming equilibrium with P_{CO_2} = 0.0003 atm.
FIGURE 12.6   Mole fraction distribution of carbonate species as a function of pH. For all calculations, activity coefficients are assumed to be unity (γ_i = 1.0).

and 10.36, the dominant carbonate species is HCO_3^- with CO_3^{2-} being present at the greatest activities above pH 10.36. However, the total carbonate in solution approaches molar quantities near pH 10 in equilibrium with carbon dioxide at this pressure, concentrations rarely seen in natural solutions. Thus, the kinetics of $CO_2(g)$ dissolution probably predominate over equilibrium predictions at these high pH values in open systems.

Information similar to Figure 12.5 can be provided without the overlying assumption of an open system or predicting equilibrium activities. Figure 12.6 is a mole fraction distribution diagram depicting the relative concentrations of the three carbonate species as a function of pH. The mole fraction is defined as the ratio of the concentrations of a given species to the sum of the concentrations of all the carbonate species. For CO_3^{2-},

$$\text{Mole fraction(carbonate)} = \frac{[CO_3^{2-}]}{[H_2CO_3^o] + [HCO_3^-] + [CO_3^{2-}]}.$$

(12.60)

The equilibrium expressions for these species in Table 12.4 are substituted appropriately and solved across pH (Lindsay, 1979). The resulting diagram (assuming that γ_i = 1) is applicable to either open or closed systems and requires equilibrium only among the solution species; equilibrium between the aqueous and gaseous phases is not required. As Figures 12.5 and 12.6 illustrates that bicarbonate ion is dominant between pH 6.36 and 10.33 with carbonic acid dominant below pH 6.36 and carbonate above pH 10.33.

In the examples above, the simple system of carbon dioxide in water was considered. Multiple component systems or other complexities can be handled in the same fashion.

12.5.3 Buffering Capacity of Soil Solutions

Because of the many acids and bases present in the soil and dissolved in the soil solution, the acid–base chemistry of soils is
FIGURE 12.7 Theoretical titration curves of an aqueous solution containing pure water ($\square$) in a closed system (no access to atmospheric $CO_2(g)$), 0.001 M total carbonate in a closed system ($\triangle$), or an open system in equilibrium with atmospheric $CO_2(g)$ at 30 Pa (0.0003 atm) (●). In all systems, the assumption is made that $\gamma_i = 1$ and the volume remains constant.

highly complicated. One of the results of this complex system is that the pH of soils and, to a smaller extent, soil solutions does not change greatly in response to inputs of acid or base. The ability of a system to resist pH changes is called the buffering capacity or buffering intensity and can be determined experimentally by titrating the solution and measuring the pH at each increment of acid or base addition. A simple, qualitative illustration of the buffering power of carbonate in water is illustrated in Figure 12.7 in which aqueous solutions are theoretically titrated with base from pH 7 to 11. In the first case, only pure water is titrated, and the solution shows little capacity to resist pH change; with each increment of base, a large pH change is noted. In the second case, a solution containing 0.001 M total carbonate is initially adjusted to pH 7 and titrated with NaOH to pH 11. In this theoretical titration, activity coefficients are ignored ($\gamma_i = 1$), but the volume is assumed to remain constant. The carbonate solution has a significant resistance to pH change (buffering capacity) compared with the pure solution. The third case in Figure 12.7 is an open system in equilibrium with atmospheric $CO_2(g)$ assuming 0.0003 atm (30 Pa). The buffering capacity of this solution is low when pH < 8, but at greater pH values, the dissolution of CO_2 into the solution radically increases the buffering.

Buffering may be quantified mathematically by defining buffering as the change in pH induced by the addition of acid or base to a solution:

$$\text{Buffering} = \frac{\Delta C_{\text{base}}}{\Delta \text{pH}} = -\frac{\Delta C_{\text{acid}}}{\Delta \text{pH}}. \tag{12.61}$$

Thus, the buffering is mathematically defined as the change in pH induced by an increment of acid or base (in mol L^{-1}) added to the system. For a monoprotic acid (HA) dissolved in water,

the buffering can be shown to be represented as (Stumm and Morgan, 1996)

$$\text{Buffering} = 2.3\left([H^+] + [OH^-] + \frac{[HA][A^-]}{[HA] + [A^-]}\right). \tag{12.62}$$

This equation defines the buffering of the system at any point in the titration of the monoprotic acid, HA. Similar expressions can be derived for mixtures of acids or for polyprotic acids.

12.5.4 Soluble Organic Acids

The chemistry of soluble organic acids in soil solutions has not been studied to the extent of inorganic acids, although detailed reviews exist (e.g., Stevenson, 1967). The relative lack of information is not because of the lack of importance of soluble organic in soils but is a reflection of the difficulty in quantitatively characterizing the organic components in solution and the dynamic nature of soil organic molecules. Many simple organic acids have been identified in solution ranging from formic and acetic acids to more complex aromatic acids such as catechin (McKeague et al., 1986). The aliphatic carboxylic acids are degraded very rapidly, but the aromatic acids tend to be more persistent.

For organic acids that can be identified, the theoretical approach to defining their chemistry is identical to that of inorganic acids. Extensive lists of acidity constants have been compiled (Martell and Smith, 2004), and these constants may be used to generate activity and mole fraction diagrams similar to Figures 12.5 and 12.6. The concepts of buffering intensity and acid neutralizing capacity of organic acids are applied in identical fashion as those of inorganic acids.

Methods also exist for quantifying the acid–base behavior of more complex organic mixtures. A direct approach is to titrate the soil solution or extract, plot the titration curve, and identify the characteristic buffering regions (Dudley and McNeal, 1987; Sposito, 2008). The resulting curves can be modeled based on hypothetical mixtures of organic acid groups, or the acid neutralizing capacity and formation functions may be determined. There is general agreement that complex organic matter in soil and in soil solution is a broad mixture of carboxylic and benzoic acids with a wide range of acidity constants.

12.6 Formation of Soluble Complexes

12.6.1 Types of Complexes

A solution complex is the close association between a central molecular component (such as a cation) with other atoms or molecules. Very often, metals or other positively charged species act as the central component attracting neutral or negatively charged ligands. In the hydrolysis of Fe^{3+} to form $Fe(H_2O)_5OH^{2+}$, the Fe^{3+} cation is acting as the central unit with water and hydroxyl acting as the ligands. This is a special case of complex formation called a solvation complex. Two other categories of complexes can be formed depending upon the strength of

bonding between the central unit and the ligand. If the inter-action between the cation and ligand is strong enough that the ligand displaces the solvation sphere, the resulting association is termed an inner-sphere complex. Typical examples of inner-sphere complexes are AlF_n^{3-n} and Fe(III)citrate. If the attraction between the cation and ligands are not strong enough to displace the hydration layer, an outer-sphere complex is formed or, sometimes, an ion pair. An inner-sphere complex can form if the heat evolved during the association exceeds the energy needed to displace the hydration sphere. If the heat evolved is less than the energy necessary to displace the water, then the hydration sheath remains intact and an outer-sphere complex results.

If a ligand occupies more than one coordination site in the complex, the ligand is referred to as multidentate. For example, two of the oxygens in oxalate can bond simultaneously with a central Fe(III) ion. Such a complex is called a chelate, and the process is chelation. The multidentate nature of the interaction can significantly increase the strength of the bond, and the resulting formation constant is much higher than ordinary complexes.

12.6.2 Hard and Soft Acid–Base Rules

Other useful concepts in predicting the association between cations and ligands are the hard and soft acid–base rules (Pearson, 1963). Hard acids and bases are those species that tend to have smaller radii and are not readily deformable (Table 12.8). Soft acids and bases are often larger and more polarizable (have a more easily deformed electron sheath). The tendency is that hard acids bond preferentially with hard bases, and soft acids bond preferentially with soft bases. Thus, Ca^{2+} would tend to bond with phosphate and carbonate rather than chloride and sulfide.

12.6.3 Rates of Formation of Solution Complexes

The rates of formation of solution complexes are often rapid, establishing equilibrium very quickly. Certain reactions, however, proceed very slowly. For example, the reaction

$$Al^{3+} + F^- \leftrightarrow AlF^{2+} \qquad (12.63)$$

requires nearly 20 min to proceed half way to completion. This is in contrast to the formation of $MnSO_4^o$, which requires 10^{-5} s.

TABLE 12.8 Hard and Soft Acids and Bases

	Hard	Intermediate	Soft
Bases	F^-, CO_3^{2-}, Cl^-, OH^-, CH_3COO^-, PO_4^{3-}, SO_4^{2-}, NH_3, $R–NH_2$, H_2O, $R–OH$, NO_3^-	SO_3^{2-}, NO_2^-, $C_6C_5NH_2$, Br^-	S^{2-}, CN^-, I^-, $R–SH$, SCN^-, $S_2O_3^{2-}$
Acids	H^+, Li^+, Na^+, K^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Al^{3+}, La^{3+}, Si^{4+}, Zr^{4+}, Th^{4+}, Th^{4+}, Cr^{3+}, Mn^{3+}, Fe^{3+}	Mn^{2+}, Fe^{2+}, Cu^{2+}, Zn^{2+}, Pb^{2+}, Bi^{3+}, Ni^{2+}, SO_2	Ag^+, Cu^+, Cd^{2+}, Hg^{2+}, Cs^+

Source: Pearson, R.G. 1963. Hard and soft acids and bases. J. Am. Chem. Soc. 85:3533.

Hydrolysis reactions generally are quite rapid for the monovalent and divalent cations but can proceed slowly for the higher charged cations. The rate of these reactions can be approximated by examining the rate of water exchange from a hydrated cation, $Me(H_2O)_x^{y+}$ (Stumm and Morgan, 1996):

$$Me(H_2O)_x^{y+} + H_2O^* \leftrightarrow Me(H_2O)_x^{y+} H_2O^*, \qquad (12.64)$$

where H_2O^* is the water being exchanged into the solvation complex. The forward rate constant in this expression is k_1, and the rate constant for the reverse reaction is k_{-1}. The exchange reaction is completed in this equation with a rate constant of k_{-w}:

$$Me(H_2O)_x^{y+} H_2O^* \rightarrow Me(H_2O)_{x-1}(H_2O^*)^{y+}. \qquad (12.65)$$
The rate of this reaction is

$$\frac{d\left[Me(H_2O)_{x-1}(H_2O^*)^{y+}\right]}{dt} = k_{-w}\left[Me(H_2O)_x^{y+}(H_2O)^*\right]. \qquad (12.66)$$

At steady state,

$$\frac{d\left[Me(H_2O)_x^{y+}(H_2O^*)\right]}{dt}$$

$$= k_1[Me(H_2O)_x^{y+}][H_2O^*] - (k_{-1} + k_{-w})\left[Me(H_2O)_x^{y+} H_2O^*\right] = 0. \qquad (12.67)$$

After further manipulation and assuming that $k_{-1} \gg k_{-w}$,

$$\frac{d\left[Me(H_2O)_{x-1}(H_2O^*)^{y+}\right]}{dt} = k_{-w}K_{OS}\left[Me(H_2O)_x^{y+}\right][H_2O^*], \qquad (12.68)$$

where $K_{OS} = k_1/k_{-1}$ is the outer-sphere complex formation equilibrium constant. Thus, the rate constant for the exchange of water in the hydration shell is estimated by $k_{-w}K_{OS}$. The same development can be used to describe the kinetics of complex formation with a ligand, L, rather than H_2O^*. The resulting equation is

$$\frac{d\left[Me(H_2O)_{x-1}L^{y+}\right]}{dt} = k_{-w}K_{OS}\left[Me(H_2O)_x^{y+}\right][L]. \qquad (12.69)$$

Omitting the waters of hydration results in the standard notation:

$$\frac{d[MeL]}{dt} = k[Me][L], \qquad (12.70)$$

where $k = k_{-w}K_{OS}$. This development illustrates the importance of the equilibrium constant for the outer-sphere complex (i.e., the energetics of the reaction) as well as the kinetics of exchange of waters of hydration surrounding the metal.

Stumm and Morgan (1996) compiled the values of k_{-w} for water exchange reactions for several metals. For Pb^{2+}, Hg^{2+}, Cu^{2+}, Ca^{2+}, Cd^{2+}, La^{3+}, Zn^{2+}, Mn^{2+}, Co^{2+}, $Fe(OH)_2^+$, and $Fe(OH)_4^-$, the values were $k_{-w} \geq 10^6$ s^{-1}. Values of k_{-w} for other metals were 2×10^2 for Fe^{3+}, 1.0 for Al^{3+}, and 5×10^{-7} for Cr^{3+}.

Sequential reactions can be "coupled" and solved. Exact analytical solutions to these models can be obtained (Sposito, 1994), but it is typical to use experimental observations to help establish simplifying assumptions.

The formation of the solution complex $CdCl^+$ in the presence of 10^{-3} mol L^{-1} Cl can be used to illustrate the application of these equations:

$$Cd(H_2O)_x^{2+} + Cl^- \leftrightarrow Cd(H_2O)_{x-1}Cl^+ + H_2O. \quad (12.71)$$
The rate of reaction can be given by

$$\frac{d\left[Cd(H_2O)_{x-1}Cl^+\right]}{dt} = K_{OS}k_{-w}\left[Cd(H_2O)_x^{2+}\right][Cl^-]$$

$$= -\frac{d\left[Cd(H_2O)_x^{2+}\right]}{dt}, \quad (12.72)$$

where

$k_{-w} = 10^{8.48}$ (s^{-1})
$K_{OS} = 10^{1.98}$ (mol L)$^{-1}$
$(k_{-w})(K_{OS}) = 10^{10.46}$ (L mol^{-1} s^{-1})

Substituting these values into the above equation and simplifying by not expressing the waters of hydration,

$$-\frac{d[Cd^{2+}]}{dt} = (10^{10.46})(10^{-3})[Cd^{2+}] = 10^{7.46}[Cd^{2+}]. \quad (12.73)$$

For a first-order reaction such as this, the half-life of the reaction (i.e., the time required for the reaction to proceed half way to completion) is equal to (ln 2) k^{-1}. Thus, the half-life for this reaction is $0.693/2.88 \times 10^7$ or 2.40×10^{-8} s. Sposito (1989) tabulated the half-lives for several solution reactions, and the values ranged from 10^{-9} s for the formation of $MnSO_4^o$ to 10^3 s for the formation of AlF^{2+}.

The relationships presented in this section demonstrate that most reactions in the soil solution are rapid enough that equilibrium can be achieved during the course of most experiments. Even the slowest example given above, the formation of AlF^{2+} in 10^3 s, will be nearly complete in less than 1 h. However, the rate of certain oxidation/reduction reactions can proceed very slowly, particularly reactions that involve oxyanions (such as arsenates or chromate) or that are not microbially catalyzed. These reactions can take days to reach completion, if at all. Therefore, knowledge of equilibrium predictions alone may be of limited utility if the kinetics of reaction are unfavorable.

12.7 Application of Thermodynamic and Equilibrium Concepts to Soil Solutions

The chemical composition and dynamics of the soil solution are reflections of all the processes, which depend upon the aqueous phase: biological activity, mineral dissolution/precipitation, adsorption/desorption, physical transport, and anthropogenic inputs. Wolt (1994) described the soil solution as "a window to chemically reacting soil systems where the intensity and distribution of chemicals in the soil aqueous phase represents the integration of multiple physical, chemical, and biological processes occurring concurrently within the soil environment." The information provided by the chemical composition is further enhanced by the knowledge of time trends and the application of kinetic and thermodynamic theories.

12.7.1 Speciation and Single-Ion Activity Determinations

The determination of free ion activities (or concentrations) for soil solution components provides a powerful interpretative tool for chemical reactions in soils. A limited number of ion activities can be determined directly (such as the H^+ activity using a glass electrode), but the rest must be approximated through rigorous calculations.

The steps in calculating ion activities and the distribution of solution species include obtaining and analyzing the soil solution, identifying the important solution species that can form, assembling relevant equilibrium constants and reactions for the formation of these species, obtaining an analytical or numerical solution for the series of equations, and calculating activity coefficients. All the steps in the calculations can be handled by any of the many geochemical models currently available (discussed later); however, understanding the chemical concepts behind the models and how the activities are determined will be helpful in properly executing the computer models and obtaining the best possible data. The following sections provide a brief review of the important chemical reactions and activity calculations.

12.7.1.1 Hydrolysis, Complexation, and Oxidation/Reduction Reactions

To help illustrate the steps involved in activity calculations, soluble Fe will be used as an example. The first step is to determine the important reactions in solution, and this can be done with the aid of some of the compilations of thermodynamic data for aqueous systems, such as Garrels and Christ (1965), Lindsay (1979), Sadiq and Lindsay (1979), and Martell and Smith (2004). Many of the metals undergo hydrolysis reactions, and Fe(III) and Fe(II) have many important hydrolysis species as indicated in Table 12.9. The distribution of these Fe(III) and Fe(II) hydrolysis species as a function of pH (Figure 12.8) shows that the predominant species will be strongly dependent upon pH with mole fractions ranging from 0.0 to over 0.9. Examination of Table 12.9 indicates that the complexes listed must be considered if $(Cl^-) > 10^{-2}$, $(F^-) > 10^{-7}$,

TABLE 12.9 Reactions and Equilibrium Constants for Selected Solution Complexes of Iron

Reaction	$\log K^o$
Fe(III) hydrolysis	
$Fe^{3+} + H_2O \leftrightarrow FeOH^{2+} + H^+$	−2.19
$Fe^{3+} + 2H_2O \leftrightarrow Fe(OH)_2^+ + 2H^+$	−5.69
$Fe^{3+} + 3H_2O \leftrightarrow Fe(OH)_3^o + 3H^+$	−13.09
$Fe^{3+} + 4H_2O \leftrightarrow Fe(OH)_4^- + 4H^+$	−21.59
Fe(II) hydrolysis	
$Fe^{2+} + H_2O \leftrightarrow FeOH^+ + H^+$	−6.74
$Fe^{2+} + 2H_2O \leftrightarrow Fe(OH)_2^o + 2H^+$	−16.04
Redox	
$Fe^{3+} + e^- \leftrightarrow Fe^{2+}$	13.04
Complexation	
$Fe^{3+} + Cl^- \leftrightarrow FeCl^{2+}$	1.48
$Fe^{3+} + F^- \leftrightarrow FeF^{2+}$	6.00
$Fe^{3+} + SO_4^{2-} \leftrightarrow FeSO_4^{2-}$	4.15
$Fe^{3+} + H_2PO_4^- \leftrightarrow FeHPO_4^- + H^+$	3.71
$Fe^{2+} + SO_4^{2-} \leftrightarrow FeSO_4^o$	2.20

FIGURE 12.8 Distribution of Fe(III) and Fe(II) hydrolysis species in solution as a function of pH.

$(SO_4^{2-}) > 10^{-5}$ mol L^{-1}. The constants in Table 12.9 and their corresponding equations can be used to solve for ionic activities.

12.7.1.2 Solution Composition Example

Consider a soil solution with the following composition: $0.2\,\mu$mol L^{-1} total Fe, 20 mmol L^{-1} total Cl, 10 μmol L^{-1} total F, 1 mmol L^{-1} total sulfate, ionic strength 0.01 mol L^{-1}, pH 6.5, and a redox potential of 600 mV. This is enough information to estimate the Fe^{2+} and Fe^{3+} activities. The solution is fairly complex and requires a few assumptions to make it solvable. The first assumption will be that the ligands will not form complexes with any cations in solution of other Fe^{2+} and Fe^{3+}. This is a poor assumption because each ligand forms a number of complexes with other cations, particularly Al^{3+}, Ca^{2+}, and Mg^{2+}. The second assumption is that the only species of Fe to be considered are those given in Table 12.9.

The approach given here is to identify all potential variables, establish the same number of independent equations as the number of variables, and solve the equations simultaneously. The system variables are the activities of H^+, OH^-, e^-, Fe^{3+}, Fe^{2+}, Cl^-, SO_4^{2-}, F^-, $FeOH^{2+}$, $Fe(OH)_2^+$, $Fe(OH)_3^o$, $Fe(OH)_4^-$, $FeOH^+$, $Fe(OH)_2^o$, $FeCl^{2+}$, FeF^{2+}, $FeSO_4^+$, and $FeSO_4^o$, for a total of 18 variables. The relevant equations include 11 complexation equations from Table 12.9 (all equations except for the formation of $FeHPO_4^+$), K_w (water dissociation equation), pH = 6.5, Eh = 600 mV (pe = 10.1), and the four mass balance equations for the components:

$$\sum Fe = [Fe^{3+}] + [Fe^{2+}] + [FeOH^{2+}] + [Fe(OH)_2^+] + [Fe(OH)_3^o]$$
$$+ [FeOH^+] + [Fe(OH)_2^o] + [FeCl^{2+}]$$
$$+ [FeF^{2+}] + [FeSO_4^+] + [FeSO_4^o], \tag{12.74}$$

$$\sum SO_4^{2-} = [SO_4^{2-}] + [FeSO_4^+] + [FeSO_4^o], \tag{12.75}$$

$$\sum Cl = [Cl^-] + [FeCl^{2+}], \tag{12.76}$$

$$\sum F = [F^-] + [FeF^{2+}]. \tag{12.77}$$

In the mass balance expressions, brackets [x] represent concentrations of species x. Activity coefficients must be calculated for each species to tie together the mass balance equations with the formation equations. Thus, there are a total of 18 equations for the 18 variables. Many methods exist for solving this system of equations including back substitution and matrix algebra. These systems can be solved by hand, but solutions are reached more rapidly using computers.

12.7.2 Geochemical Models

Over the past decades, scientists and research groups have recognized the need for computer programs to solve chemical

equilibrium systems, and several computer models have been established. Models vary widely in their construction and composition as well as their intended use (Baham, 1984; Melchior and Bassett, 1990; van der Lee and de Windt, 2001; Hummel, 2005). Many of the models are based upon single-ion activities, single-ion activity coefficients, and formation constants; Pitzer's equations for applications at high ionic strength; or a free energy minimization approach.

12.7.2.1 Formation Constant Approach

In Section 12.7.1.2, an example was given outlining the formation constant approach to determine single-ion activities in soil solutions. Several series of published models take this same approach. The WATEQ series (Truesdall and Jones, 1974; Ball et al., 1979) was developed by the U.S. Geological Survey to compute single-ion activities to predict the fate of critical elements in geochemical environments. Emphasis was placed on obtaining a well-documented thermodynamic database with the best available equilibrium constants; a reaction would be kept out of the database if the constant was estimated or suspected to be of poor quality. The mathematical solution method was back substitution and required recompilation of the programming code if new reactions were added or if constants were changed. The MINEQL series (Westall et al., 1976) was developed using the mathematical approach of REDEQL (Morel and Morgan, 1972) to solve equilibrium problems and provide information about trends in observed data. The mathematical solution method is rapid and efficient, but the thermodynamic database was not rigorously reviewed. The model SOILCHEM (Sposito and Coves, 1988) was an extension of the MINEQL model with emphasis on expanding the database. Some smaller models have been developed, such as SOILSOLN (Wolt, 1989) and CALPHOS (Adams, 1971), for very specific (but limited) applications. SOILSOLN was designed as a teaching tool with an easy-to-use interface and embedded graphics.

12.7.2.2 High Ionic Strength Models

The general approach in the models described in Section 12.7.2.1 is the combination of equilibrium constant expressions with mass balances. The impact of ionic strength (and activity coefficients) is disregarded or single-ion activity coefficients are calculated. The single-ion activity coefficient is not rigorously defined in thermodynamic theory, and the equations used to approximate activity coefficients are subject to error, particularly at high ionic strength. A special approach must be taken for aqueous solutions with high-salt concentrations (ionic strength greater than 0.5 mol L^{-1}). One such approach is to use the Pitzer equations (Pitzer, 1979) for calculation of single-ion activity coefficients, and at least two published models currently use this approach. Felmy and Weare (1995) discussed their model and experimental results of simple systems with high ionic strengths. The agreement between theory and experimental determinations is promising. The C-SALT model (Smith et al., 1995) also uses the Pitzer equations. The model has been tested against experimental data.

The Pitzer equations require a relatively large number of parameters that are specific to the ions and systems under consideration. The number of required parameters increases rapidly as the systems become more complex. The Pitzer, Davies, and Debye–Hückel equations calculate single-ion activity coefficients. Unfortunately, these activity coefficients cannot be defined unambiguously because they are dependent upon a clear, thermodynamic definition of single-ion concentrations. As stated by Sposito (1994) when discussing the activity coefficients for a metal ion, γ_M, and a ligand, γ_L, "For γ_M and γ_L to have chemical significance, the species molalities, m_M and m_L, must have a well-defined operational meaning. Thus, the single-ion activity coefficient has no meaning apart from the set of operational procedures used to define ionic species and to determine their concentrations in an aqueous solution." Although the determination of single-ion activities can provide useful information, single-ion activity coefficients cannot be experimentally determined and do not have a thermodynamic foundation.

12.7.2.3 Solving Example Problem with Visual MINTEQ

The geochemical model, MINTEQ, and later MINTEQA2 (Allison et al., 1990), were developed by merging the mathematics and computer code from MINEQL with the database from the WATEQ series. Although the MINTEQ database is not as extensive as SOILCHEM's, all values were fully documented as to their source and reason for selection. Visual MINTEQ was developed to provide a graphic interface for MINTEQA2 version 4 (Gustafsson, 2009) as well as expanding the database. Visual MINTEQ provides solution speciation, mass transfer through precipitation and dissolution of solid phases, ion adsorption, ion exchange, redox, and humic complexation models, and gas phase calculations.

The hypothetical analytical data for the example problem in Section 12.7.1.2 were entered into a Visual MINTEQ input file, and the program executed. The resulting activities (Table 12.10)

TABLE 12.10   Activities of Selected Aqueous Species Calculated Using Visual MINTEQ Version 2.61 for the Example Solution Composition Given in Section 12.7.1.2

Species	Log (Activity)	Species	Log (Activity)
Fe^{3+}	−14.00	Fe^{2+}	−11.11
$Fe(OH)^{2+}$	−9.52	$FeOH^+$	−14.00
$Fe(OH)_2^+$	−6.75	$Fe(OH)_2^o$	−18.60
$Fe(OH)_3^o$	−9.50	$FeSO_4^o$	−11.89
$Fe(OH)_4^-$	−10.70	FeF^+	−14.94
FeF^{2+}	−13.00	$FeCl^+$	−13.05
FeF_2^+	−13.43	F^-	−5.05
FeF_3^o	−15.43	SO_4^{2-}	−3.18
$FeSO_4^+$	−12.92	Cl^-	−1.74
$FeCl^{2+}$	−14.26		

Source: Gustafsson, J.P. 2009. Visual MINTEQ version 2.61. http://www.lwr.kth.se/English/OurSoftware/vminteq/, accessed on May 16, 2011.

show that the hydrolysis species of Fe(III) and Fe(II) are much more important than the chloro, fluoro, and sulfate species. This is because these ligands react only with the unhydrolyzed cations, and, in the case of Fe(III), the activity of Fe^{3+} is very low. In the case of Fe(II), the ligand concentrations simply are not high enough to become the predominant solution species. (It is to be noted that the program was executed with the specification that supersaturated solid phases would not be allowed to precipitate. Many solid phases were supersaturated, and allowing their precipitation would have changed the results.)

The comparison of the Fe(III) and Fe(II) species also is worth noting. In Table 12.9, the constant for the equilibrium between Fe^{3+} and Fe^{2+} suggests that Fe^{2+} will be present are higher activities than Fe^{3+} when the pe < 13 (770 mV). In this case, Fe^{2+} is nearly 1000 times greater than Fe^{3+}, but the Fe(III) hydrolysis species are by far the predominant Fe solution species. At this pH, the oxidation/reduction potential would have to be pe < 6.0 (355 mV) before the predominant Fe(II) species is present at a greater activity than the predominant Fe(III) species.

12.7.3 Oxidation/Reduction Reactions

Chemical reactions involving oxidation and reduction are important in all biological systems, and soils are no exception. In all soils, localized areas can be found that are highly oxidized and highly reduced. Areas of reduction generally are associated with small microsites that are saturated with water and have restricted $O_2(g)$ diffusion. Microbial activity within these sites rapidly depletes the available oxygen, and the redox potential of the soil solution decreases. The ability to predict the impact of changes in redox on soil solution composition is a useful tool.

The first step in handling oxidation/reduction equilibria in soil solution is defining the limits of stability of aqueous systems. If a solution is subject to a high oxidizing potential, then the water spontaneously can be degraded into oxygen:

$$0.5H_2O(l) = H^+ + e^- + 0.25O_2(g) \qquad (12.78)$$
with an equilibrium constant expression:

$$K^o = \frac{(H^+)(e^-)\left(O_2(g)\right)^{0.25}}{(H_2O)^{0.5}} = 10^{-20.78}. \qquad (12.79)$$

Substituting, rearranging, and solving for pe in terms of pH,

$$pe = 20.78 + 0.25\log(O_2) - pH. \qquad (12.80)$$

The pe at which water spontaneously decomposes to oxygen gas would correspond to $O_2(g)$ pressure of 1 atm or pe = 20.78 − pH. Using the combined parameter, pe + pH, the upper oxidizing limit of the stability field of water would be

$$pe + pH = 20.78. \qquad (12.81)$$

A strongly reducing potential can generate hydrogen gas:

$$H^+ + e^- \leftrightarrow 0.5H_2(g). \qquad (12.82)$$
Again solving for pe,

$$pe = -0.5\log\left(H_2(g)\right) - pH. \qquad (12.83)$$

At 1 atm $H_2(g)$, this reduces to pe = −pH. Again converting to the combined parameter, pe + pH,

$$pe + pH = 0. \qquad (12.84)$$

In a plot of pe versus pH, the region between the lines pe = −pH and pe = 20.78 − pH represents the stability field for water. Water is thermodynamically unstable at potentials outside this region. Another important aspect of these equations is the equilibrium partial pressures of $H_2(g)$ and $O_2(g)$ at typical redox potentials in soil solutions. For example, highly reduced soils seldom have redox potentials below pe + pH = 4, corresponding to $P_{H_2} = 10^{-8}$ atm. Measured redox potentials in fully oxidized soils seldom exceed pe + pH 18, and equilibrium at this potential would require $10^{-11.23}$ atm $O_2(g)$. If equilibrium were rapidly established with these gases, then the partial pressures of hydrogen and oxygen would be expected to be quite small in all situations. An equilibrium approach can be used to investigate many redox reactions in soil solutions. The Fe(III)/Fe(II) system was discussed in a prior section, and many other redox active species exist in soil solutions including Cu^{2+}, Mn^{2+}, and CrO_4^{2-}. Chromium is an environmentally important metal and has an interesting redox behavior. The Cr(III) species is considered environmentally less hazardous than the Cr(VI), which is closely regulated. Published equilibrium constants can be used to determine the redox potential at pH 7 at which the predominant Cr(III) species, $Cr(OH)_2^+$, converts to the predominant Cr(VI) species, CrO_4^{2-}. From the MINTEQ database, the following reaction and constant were obtained:

$$CrO_4^{2-} + 6H^+ + 3e^- \Leftrightarrow Cr(OH)_2^+ + 2H_2O \quad \log K^o = 67.38. \qquad (12.85)$$
The expression for the equilibrium constant, converted to logarithms, would be

$$\log\left[\frac{\left(Cr(OH)_2^+\right)}{(CrO_4^{2-})}\right] + 6\,pH + 3\,pe = 67.38. \qquad (12.86)$$

The redox potential at which Cr(III) converts to Cr(VI) occurs when the predominant species of each oxidation state of Cr have equal activities, $(Cr(OH)_2^+) = (CrO_4^{2-})$. The ratio of these activities would equal unity, the logarithm of which is 0. Therefore, after dividing by 3,

$$2\,pH + pe = 22.46 \qquad (12.87)$$

or, solving for pe + pH,

$$pe + pH = 22.46 - pH \qquad (12.88)$$

and, at pH = 7,

$$pe + pH = 15.46. \qquad (12.89)$$

This is a moderately reducing condition for soil solutions, roughly the same redox potential at which denitrification occurs (Lindsay, 1979).

12.7.4 Successful Applications of Geochemical Modeling to Soil Solutions

The application of equilibrium thermodynamics to soil solutions will have several requirements for success, and the definition of success will depend upon individual interpretations. The kinetics of some reactions in soil solutions were discussed in Section 12.6.3; most reactions were found to proceed quickly, but others are quite slow. Therefore, care must be taken to apply equilibrium thermodynamics only to the systems having enough time to equilibrate, and this is dependent upon the method of sample collection. For example, miscible displacement methods often have equilibration periods of less than 24 h, which is not long enough for some solid-phase equilibria or redox reactions involving oxyanions. However, most of the field methods should be adequate.

The success of applying a model to a chemical system will increase as more information is known. One of the important areas of progress in geochemical modeling in recent years has been the addition of aluminum–phosphate speciation and empirical models for evaluating the impact of soluble organic matter.

A critical aspect of employing a geochemical model is experimental validation. Models have been validated by published laboratory tests followed by extending the model to similar systems in natural settings. Felmy and Weare (1995) incorporated Pitzer's equations into an ion-interaction model, the purpose of which was to allow chemical speciation in high ionic strength solutions. The Davies equation for activity coefficients was found to inadequately predict $\gamma_\pm$ for many salts at ionic strengths as low as 0.2 mol L^{-1} for 1:1 electrolytes and 0.05 mol L^{-1} for 2:1 electrolytes (Figure 12.9). The parameters for the ion-interaction model were obtained experimentally and applied to several systems, including $Na_2B_4O_7$–Na_2SO_4–H_2O, $Na_2B_4O_7$–Na_2CO_3–H_2O, and $NaBO_2$–$NaCl$–H_2O systems. Salt concentrations were varied, and other activities measured. The agreement between modeling predictions and experimental results were ±10%, even in the $NaBO_2$–$NaCl$–H_2O system (Figure 12.10) with very high borate concentrations and ionic strengths as high as 14 mol L^{-1}.

The effect of redox on the solubility of Fe in soil and aqueous systems has been a subject of study for decades. The presence of mixed valence state oxides has been observed and implied, and extensive equilibrium studies have been published. One of the
FIGURE 12.9 Changes in experimentally determined mean activity coefficients ($\gamma_\pm$) for various electrolytes compared with those generated by the Davies equation. Measured values are symbols, and predicted values are lines. (From Felmy, A.R., and J.H. Weare. 1995. The development and application of aqueous thermodynamic models: The specific ion-interaction approach. *In* R. Loeppert et al. (eds.) Chemical equilibrium and reaction models. Soil Science Society of America Special Publications No. 42. ASA, Madison, WI.)
FIGURE 12.10 The system $NaBO_2$–$NaCl$–H_2O at 20°C. Experimental data of Skvortsov et al. (1976) are shown as symbols, and the model predictions of Felmy and Weare (1995) are represented as lines.

more thorough studies involved the controlled reduction of ferric oxides (Brennan and Lindsay, 1998). Figure 12.11 is a redrafting of the experimental data in conjunction with the solubility constants of the solid phases from the Visual MINTEQ database. The implications of the original publication are unchanged despite some significant differences between the MINTEQ constants and those used by Brennan and Lindsay (1998). The observed solubilities of Fe^{2+} as a function of redox had a slope consistent with a solid phase with a stoichiometry of $Fe(II)Fe(III)_2O_4$. Although the molecular structure and Fe valence states of the resultant precipitate were not verified, the authors
FIGURE 12.11 Oxidation/reduction experiments under controlled conditions with different starting materials or different incubation periods. The open squares began with hematite, the open circles began with ferrihydrite, and the filled triangles were aged for 15 days. (From Brennan, E.W., and W.L. Lindsay. 1998. Reduction and oxidation effect on the solubility and transformation of iron oxides. Soil Sci. Soc. Am. J. 62:930–937.)

suggested that Fe solubility was being controlled by an amorphous form of magnetite, Fe_3O_4(amorphous).

12.7.5 Limitations to Applying Geochemical Models to Soil Solutions

Four major limitations exist in the application of equilibrium geochemical models to soil solutions: the dynamic (nonequilibrium) nature of soils, poorly defined equilibria, limitations in the analytical chemistry, and lack of knowledge of how to accurately handle soluble organic compounds. The ever-changing nature of soils naturally leads to nonequilibrium conditions. Although equilibrium within the soil solution may be attained quickly, solid and gas phases often establish equilibrium at a slow rate, if at all. Unfortunately, these systems have a very strong impact on the composition of the soil solution. Understanding the degree of nonequilibrium and the rate at which a steady state is being approached can be discerned by sampling the soil solution over time and monitoring the progress of the chemical reactions. Suarez (1995) discussed the merits of a nonequilibrium approach to modeling the carbonate system.

The problem of poorly defined equilibria arises when information about the system is lacking or if the database accompanying the geochemical model does not contain all the equilibrium constants to fully characterize important reactions. If data are severely lacking, then a speciation approach may not be possible. However, estimating experimental parameters or equilibrium constants may be an acceptable alternative. Limitations in analytical chemistry (quantification limits, capability to analyze certain species) must be dealt with in the same way.

As discussed in previous sections, soluble organic compounds are among the most important components in the soil solution,

and we have the least thermodynamic information about them. These compounds can be very complex and contain a wide range of functional groups and molecular chemical environments, making it difficult to approximate complexation constants. Thus, a decision must be made either to ignore the effects of soluble organics completely because their impact cannot be quantified exactly or to apply estimates of the constants. The latter approach has been applied with some success, including the addition of an organic component to Visual MINTEQ.

12.8 Current Status and Future Research Directions

This review of the chemistry of the soil solution assumed a distinct theoretical approach and did not focus on some of the excellent, recent advances in other aspects of the science. Topics not covered include colloidal chemistry (both inorganic and organic), spectroscopic approaches to identifying important complexes in the soil solution, salinity, xenobiotics in soil solutions, and heavy metals. Most of these topics are covered in other chapters.

The study of the soil solution has its origins in agriculture, and a great portion of soil chemical research remains agriculturally oriented. Many challenges exist in which soil chemists will play a pivotal role including managing soil acidity, growing crops in arid regions with limited or poor quality irrigation water, adapting to the inevitable trend toward lower quality fertilizers, and contributing to the development of truly sustainable agricultural systems.

Although soil chemistry has its history and future firmly rooted in agriculture, soil chemists are increasingly finding a niche in other, less traditional research areas. Geochemists, environmental engineers, hydrologists, and chemical engineers are finding that soil chemists make excellent research partners in solving environmental and production problems. Working knowledge of and the ability to use new technologies have allowed soil chemists to explore new areas: molecular-level spectroscopy to quantify the chemistry of surfaces, complexation reactions in solution, and chemical associations in both the solid and solution phases; analytical instrumentation to quantify ultratrace quantities of contaminants; and molecular genetics of microorganisms to help answer difficult ecological and environmental questions.

Kinetics and Mechanisms of Soil Chemical Reactions

Donald L. Sparks
University of Delaware

13.1 Introduction

Since its inception in the mid-1850s, soil chemistry has focused on the macroscopic, equilibrium aspects of soil chemical reactions (CRs) and processes. From these studies, much was learned about important soil chemical processes, including sorption, desorption, precipitation, complexation, dissolution, and oxidation/reduction. However, such investigations do not convey information on reaction rates or reaction mechanisms. In the past three decades, as concerns and interests about soil and water quality have increased, soil and environmental chemists, environmental and chemical engineers, and geochemists have increasingly realized that reactions in subsurface environments are time dependent. Thus, to accurately predict the fate, mobility, speciation, and bioavailability of environmentally important plant nutrients, trace elements, radionuclides, and organic chemicals in soils, one must understand the kinetics and mechanisms of the reactions.

While major progress has been made in better understanding the kinetics of soil chemical processes, much uncertainty remains. In part, this is due to the complex, heterogeneous nature of natural materials such as soils. However, with the development of kinetic techniques that can be used to measure a wide range of timescales, time-dependent models that can describe both CR and mass transfer processes, and the employment of state-of-the-art in situ spectroscopic and microscopic surface techniques in combination with rate studies, major advances are being made in understanding the kinetics and mechanisms of

soil CRs. Arguably, this will be a major leitmotif in soil chemistry research for decades to come.

In this review, the application of chemical kinetics to heterogeneous systems, such as soils and soil components (clay minerals, organic matter, metal hydr(oxides), and humic substances), with emphasis on sorption/release processes will be discussed. A critical review of kinetic models that can be used to describe reaction rates on heterogeneous surfaces will be covered. The review will also present discussions on the rates of important soil CRs and processes including inorganic and organic sorption/desorption, dissolution, and redox. For additional details on these topics and other aspects of kinetics of soil chemical and geochemical processes, the reader should consult a number of recent books and monographs (Sparks, 1989, 1995, 2002, 2005; Sparks and Suarez, 1991; Stumm, 1992; Schwarzenbach et al., 1993; Sposito, 1994; Grossl et al., 1997; Matocha et al., 2005; Borda and Sparks, 2008).

13.2 Timescales of Soil Chemical Processes

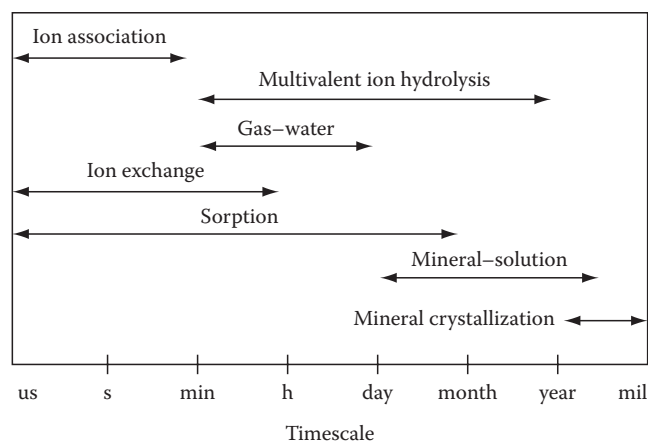
A variety of CRs occur in soils and often in combination with one another. Reaction timescales can vary from microseconds to milliseconds for many ion association and some ion exchange, sorption, and redox reactions to years for many mineral solution and mineral crystallization phenomena and for some sorption/release reactions (Figure 13.1). Ion association reactions include ion pairing, inner- and outer-sphere complexation,


FIGURE 13.1 Time ranges required to attain equilibrium by different types of reactions in soil environments. (Reprinted with permission from Amacher, M.C. 1991. Methods of obtaining and analyzing kinetic data, p. 19–59. *In* D.L. Sparks and D.L. Suarez (eds.) Rates of soil chemical processes. SSSA, Madison, WI.)

and chelation in solution. Gas–water reactions involve gaseous exchange across the air–liquid interface. Ion exchange reactions occur when cations and anions are adsorbed (outer-sphere complexation) and desorbed from soil surfaces by electrostatic attractive forces. Ion exchange reactions are reversible and stoichiometric. Sorption reactions can involve adsorption processes, including partitioning, outer-sphere and inner-sphere complexation, and multinuclear complexation (e.g., surface precipitation). Mineral–solution reactions include precipitation/dissolution of minerals and coprecipitation reactions in which small constituents become a part of mineral structures (Sparks, 1989; Amacher, 1991).

The type of soil component can drastically affect the reaction rate. For example, sorption reactions are often more rapid on clay minerals, such as kaolinite and smectites, than on vermiculitic and micaceous minerals. This is in large part due to the availability of sites for sorption. For example, kaolinite has readily available planar external sites, and smectites have primarily internal sites that are also quite available for retention of sorbates. Thus, sorption reactions on these soil constituents are often quite rapid, even occurring on timescales of seconds and milliseconds (Sparks, 1989, 2005).

On the other hand, vermiculite and micas have multiple sites for retention of metals and organics, including planar, edge, and interlayer sites, with some of the latter sites being partially to totally collapsed. Consequently, sorption and desorption reactions on these sites can be slow, tortuous, and mass transfer controlled. Often, an apparent equilibrium may not be reached even after several days or weeks. Thus, with vermiculite and mica, sorption can involve two to three different reaction rates: high rates on external sites, intermediate rates on edge sites, and low rates on interlayer sites (Jardine and Sparks, 1984; Comans and Hockley, 1992).

Metal sorption reactions on oxides, hydroxides, and humic substances depend on the type of surface and metal being

studied, but the CR rate appears to be rapid. For example, CR rates of metals and oxyanions on goethite occurred on millisecond timescales (Zhang and Sparks, 1989, 1990a, 1990b; Grossl et al., 1994, 1997). Reaction rates of redox processes can also be very rapid. For example, Parikh et al. (2008) found that 50% of the initial reaction process for As(III) oxidation on Mn oxides occurred in 1 min. Half-times for divalent Pb, Cu, and Zn sorption on peat ranged from 5 to 15 s (Bunzl et al., 1976). A number of studies have shown that heavy metal sorption on oxides (Bruemmer et al., 1988; Ainsworth et al., 1994; Scheidegger and Sparks, 1996a; Scheidegger et al., 1998) and clay minerals (Lövgren et al., 1990) increases with longer residence times. The mechanism for these lower reaction rates is not well understood but has been ascribed to diffusion phenomena, sites of lower reactivity, and surface nucleation/precipitation (Scheidegger and Sparks, 1996b; Sparks, 1998, 1999a, 1999b). Recent findings on slow metal retention rates and mechanisms at the mineral/water interface will be discussed later.

Sorption/desorption of metals and organic chemicals on soils is often very slow, which has been attributed to diffusion into micropores of inorganic minerals and into humic substances, retention on sites of varying reactivity, and surface nucleation/precipitation (Sparks 1989, 1999a, 1999b, 2002, 2005; Scheidegger and Sparks, 1996b; Matocha et al., 2005; Borda and Sparks, 2008). These reactions will be discussed in more detail later.

13.3 Application of Chemical Kinetics to Heterogeneous Surfaces

The study of chemical kinetics, even in homogeneous systems, is complex and often arduous. When one attempts to study the kinetics of reactions in heterogeneous systems such as soils, sediments, and even soil components, such as clay minerals, hydrous oxides, and humic substances, the difficulties are greatly magnified. This is largely due to the complexity of soils that are made up of a mixture of inorganic and organic components. These components often interact with each other and display different types of sites with various reactivities for inorganic and organic sorptives. Moreover, the variety of particle sizes and porosities in soils and sediments further adds to their heterogeneity. In most cases, both chemical kinetics and multiple transport processes are occurring simultaneously. Thus, the determination of chemical kinetics, which can be defined as the investigation of rates of CRs and of the molecular processes by which reactions occur where transport is not limiting (Gardiner, 1969), is extremely difficult, if not impossible, in heterogeneous systems. In these systems, one is studying kinetics, which is a generic term referring to time-dependent or nonequilibrium processes. Thus, apparent and nonmechanistic rate laws and rate parameters are determined (Skopp, 1986; Sparks, 1989).

13.3.1 Rate-Limiting Steps

Both transport and CR processes can affect the reaction rates in the subsurface environment. Transport processes include
Liquid   Film   Solid

FIGURE 13.2 Transport processes in solid–liquid soil reactions—nonactivated processes: (1) transport in the soil solution, (2) transport across a liquid film at the solid–liquid interface, (3) transport in a liquid-filled macropore—activated processes, (4) diffusion of a sorbate at the surface of the solid, (5) diffusion of a sorbate occluded in a micropore, (6) diffusion in the bulk of the solid. (Reprinted from Aharoni, C., and D.L. Sparks. 1991. Kinetics of soil chemical reactions: A theoretical treatment, p. 1–18. *In* D.L. Sparks and D.L. Suarez (eds.) Rates of soil chemical processes. SSSA, Madison, WI.)

(Aharoni and Sparks, 1991) the following: (1) transport in the solution phase; (2) transport across a liquid film at the particle/liquid interface (film diffusion [FD]); (3) transport in liquid-filled macropores (>2 nm), all of which are nonactivated diffusion processes and occur in mobile regions; (4) particle diffusion (PD) processes, which include diffusion of sorbate occluded in micropores (<2 nm, pore diffusion) and along pore wall surfaces (surface diffusion); and (5) diffusion processes in the bulk of the solid, all of which are activated diffusion processes (Figure 13.2). Pore and surface diffusion within the immediate region can be referred to as interaggregate (interparticle) diffusion while that in the solid is intraaggregate diffusion. The actual CR at the surface, for example, adsorption, is usually instantaneous. The slowest of the CR and transport processes is rate limiting.

13.3.2 Rate Laws

There are two important reasons for investigating the rates of soil chemical processes (Sparks, 1989, 1995, 1998, 1999a, 1999b, 2002) (1) to determine how rapidly reactions attain equilibrium and (2) to infer information on reaction mechanisms. One of the most important aspects of chemical kinetics is the establishment of a rate equation or law. By definition, a rate law is a differential equation. For the following reaction (Bunnett, 1986; Sparks, 1989, 1995, 1998, 1999a, 1999b, 2002),

$$aA + bB \rightarrow yY + zZ, \qquad (13.1)$$
the rate is proportional to some power of the concentrations of reactants *A* and *B* and/or other species (*C*, *D*, etc.) in the

system, and *a*, *b*, *y*, and *z* are stoichiometric coefficients and are assumed to be equal to 1 in the discussion that follows on rate laws. The power to which the concentration is raised may equal 0 (i.e., the rate is independent of that concentration), even for reactant *A* or *B*. Rates are expressed as a decrease in reactant concentration or an increase in product concentration per unit time. Thus, the rate of conversion of reactant *A* above, which has a concentration [*A*] at any time *t*, is $(-d[A]/(dt))$ while the rate with regard to product *Y* having a concentration [*Y*] at time *t* is $(d[Y]/(dt))$.

The rate expression for Equation 13.1 is therefore as follows:

$$\frac{d[Y]}{dt} = -\frac{d[A]}{dt} = [A]^{\alpha}[B]^{\beta}, \qquad (13.2)$$

where
  k is the rate constant
  α and β are the orders of the reaction with respect to reactants *A* and *B*, respectively, and can be referred to as a partial orders for the total reaction

These orders are experimentally determined and not necessarily integral numbers. The sum of all the partial orders (α and β) is the overall order (*n*) of the total reaction and may be expressed as follows:

$$n = \alpha + \beta + \cdots \qquad (13.3)$$

Once the values of α, β, etc., are determined experimentally, the rate law is defined. Reaction order provides only information about the manner in which rate depends on concentration. Order does not mean the same as molecularity, which concerns the number of reactant particles (atoms, molecules, free radicals, or ions) entering into an elementary reaction. One can define an elementary reaction as one in which no reaction intermediates have been detected or need to be postulated to describe the CR on a molecular scale. An elementary reaction is assumed to occur in a single step and to pass through a single transition state (Bunnett, 1986).

To demonstrate that a reaction is elementary, one can use experimental conditions that are different from those employed in determining the reaction rate law. For example, if one conducted kinetic studies using a flow technique with set steady-state flow rates, one could see if reaction rate and rate constants changed with flow rate. If they did, one would not be determining mechanistic rate laws (see definition below).

Rate laws serve three purposes: (1) they assist one in predicting the reaction rate, (2) mechanisms can be proposed, and (3) reaction orders can be ascertained. There are four types of rate laws that can be determined for soil chemical processes (Skopp, 1986): mechanistic, apparent, transport with apparent, and transport with mechanistic. Mechanistic rate laws assume that only chemical kinetics are operational and transport phenomena are not occurring. Consequently, it is difficult to determine mechanistic rate laws for most soil chemical systems due

to the heterogeneity of the system caused by different particle sizes, porosities, and types of retention sites. There is evidence that with some kinetic studies, using chemical relaxation techniques (Sparks, 1989; Sparks and Zhang, 1991), that mechanistic rate laws are determined or closely approximated since the agreement between equilibrium constants calculated from both kinetic and equilibrium studies are comparable (Hachiya et al., 1984; Tang and Sparks, 1993). Recent studies using molecular scale in situ spectroscopic methods such as attenuated total reflectance Fourier transform infrared (ATR–FTIR) and quick x-ray absorption spectroscopy (QXAS; Parikh et al., 2008; Ginder-Vogel et al., 2009; Landrot et al., 2010) to measure rapid initial reaction rates also show that chemical kinetics are being measured, and, thus, mechanistic rate laws can be proposed.

Since natural materials are heterogeneous and transport processes often affect the reaction rate, apparent rate laws are usually determined for such systems. Apparent rate laws include both chemical kinetics and transport-controlled processes. Thus, soil structure, stirring, mixing, and flow rate all would affect the kinetics. Transport with apparent rate laws emphasizes transport-limited phenomena. One often assumes first-order or zero-order reactions (see the following discussion on reaction order). In determining transport with mechanistic rate laws, one attempts to describe simultaneously transport-controlled and chemical kinetics phenomena. One is thus trying to explain accurately both the chemistry and physics of the system.

13.3.3 Determination of Reaction Order and Rate Constants/Coefficients

There are three basic ways to determine rate laws and rate constants/coefficients (Bunnett, 1986; Skopp, 1986; Sparks, 1989, 1995, 1998, 1999a, 1999b, 2002): (1) initial rates, (2) directly using integrated equations and graphing the data, and (3) using nonlinear least-squares analysis.

Let us assume the following elementary reaction between species *A*, *B*, and *Y*:

$$A + B \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Y. \tag{13.4}$$
A forward reaction rate law can be written as

$$\frac{d[A]}{dt} = -k_1[A][B], \tag{13.5}$$

where
k_1 is the forward rate constant
α and β (see Equation 13.2) are each assumed to be 1

The reverse reaction rate law for Equation 13.4 is

$$\frac{d[A]}{dt} = +k_{-1}[Y], \tag{13.6}$$

where k_{-1} is the reverse rate constant.

Equations 13.5 and 13.6 are only applicable far from equilibrium where back or reverse reactions are insignificant. If both forward and reverse reactions are occurring, Equations 13.5 and 13.6 must be combined such that

$$\frac{d[A]}{dt} = -k_1[A][B] + k_{-1}[Y]. \tag{13.7}$$

Equation 13.7 applies the principle that the net reaction rate is the difference between the sum of all reverse reaction rates and the sum of all forward reaction rates.

One way to ensure that back reactions are not important is to measure initial rates. The initial rate is the limit of the reaction rate as time reaches zero. With an initial rate method, one plots the concentration of a reactant or product over a short reaction time period during which the concentrations of the reactants change so little that the instantaneous rate is hardly affected. Thus, by measuring initial rates, one could assume that only the forward reaction in Equation 13.4 predominates. This would simplify the rate law to that given in Equation 13.5, which, as written, would be a second-order reaction, first order in reactant *A* and first order in reactant *B*. Equation 13.5, under these conditions, would represent a second-order irreversible elementary reaction. To measure initial rates, one must have available a technique that can measure rapid reactions, such as a chemical relaxation method or a rapid molecular scale spectroscopic technique and an accurate analytical detection system to determine product concentrations. Recently, Parikh et al. (2008) used a novel real-time ATR–FTIR spectroscopic technique to measure the initial rates of As(III) oxidation on Mn oxides. Using a rapid scan technique, IR spectra were collected with a time resolution of up to 2.55 s. Ginder-Vogel et al. (2009) and Landrot et al. (2010) have employed state-of-the-art QXAS to investigate initial rates of As(III) oxidation on hydrous Mn oxide and Cr(III) oxidation on hydrous Mn oxide, respectively. In the study of Ginder-Vogel et al. (2009), QXAS scans were collected every 0.98 s, while scans were collected every 0.75 s in the study of Landrot et al. (2010).

Integrated rate equations can also be used to determine rate constants/coefficients. If one assumes that reactant *B* in Equation 13.5 is in large excess of reactant *A*, which is an example of the method of isolation to analyze kinetic data, and $Y_o = 0$, where Y_o is the initial concentration of product *Y*, Equation 13.5 can be simplified to

$$\frac{d[A]}{dt} = -k_1'[A], \tag{13.8}$$

where $k_1' = k_1[B]$.

The first-order dependence of [*A*] can be evaluated using the integrated form of Equation 13.8 using the initial conditions at $t = 0$, $A = A_o$:

$$\log[A]_t = \log[A]_o - \frac{k_1' t}{2.303}. \tag{13.9}$$
FIGURE 13.3 Initial reaction rates depicting the first-order dependence of Mn^{2+} sorption as a function of time for initial Mn^{2+} concentrations ($[Mn^{2+}]_o$) 25 and 40 μM. (Reprinted from Fendorf, S.E. et al. 1993. Soil Sci. Soc. Am. J., 57:57–62. With permission of the Soil Science Society of America.)

The half-time ($t_{1/2}$) for the above reaction is equal to $0.693/k_1'$ and is the time required for half of reactant A to be consumed.

If a reaction is first order, a plot of log $[A]_t$ versus t should result in a straight line with a slope = $k_1'/2.303$ and an intercept of log $[A]_o$. An example of first-order plots for Mn^{2+} sorption on δ-MnO_2 at two initial Mn^{2+} concentrations, $[Mn^{2+}]_o$ (25 and 40 μM), is shown in Figure 13.3. One sees that the plots are linear at both concentrations, which would indicate that the sorption process is first order. The $[Mn^{2+}]_o$ values obtained from the intercepts in Figure 13.3 were 24 and 41 μM, which are in good agreement with the two $[Mn^{2+}]_o$ values, and the rate constants were 3.73×10^{-3} and 3.75×10^{-3} s^{-1}, respectively. The fact that the rate constants do not significantly change with concentration is a good indication that the reaction in Equation 13.8 is first order under the imposed experimental conditions.

It is dangerous to conclude that a particular reaction order is correct, based simply on the conformity of data to an integrated equation. As illustrated above, multiple initial concentrations that vary considerably should be employed to see if the rate is independent of concentration. One should also test multiple integrated equations. It may also be useful to show that reaction rate is not affected by a species whose concentration does not change considerably during an experiment, such as substances not consumed or present in large excess (Bunnett, 1986; Sparks, 1989, 1991, 1995, 1998, 1999a, 1999b).

Least-squares analysis can also be used to determine rate constants/coefficients. With this method, one fits the best straight line to a set of points that are linearly related as $y = mx + b$, where y is the ordinate and x is the abscissa datum point, respectively. The slope (m) and the intercept (b) can be calculated by least-squares analysis.

When kinetic data are plotted, curvature may be observed due to an incorrect assumption of reaction order. If first-order kinetics is assumed and the reaction is really second order, downward curvature results. If second-order kinetics is assumed but the reaction is first order, upward curvature is observed. Curvature can also be due to fractional, third, higher, or mixed reaction order. Nonattainment of equilibrium often results in downward curvature. Temperature changes during the study can also cause curvature; thus, it is important that temperature be accurately controlled during a kinetic experiment.

13.4 Kinetic Models

13.4.1 Ordered Models

First-order kinetic models often describe reactions at the soil mineral/water interface. Both single first-order and multiple first-order reactions have been described by many investigators (Sparks, 1989, 1991, 2002; Sparks et al., 1993).

It is not uncommon to observe biphasic kinetics, namely, a rapid reaction rate followed by a much slower reaction rate. Such data can often be described by two first-order reactions. Some investigators have interpreted such biphasic kinetics to suggest reactions on two types of sites, such as external, readily accessible sites (Slope 1) and internal, difficult to access sites (Slope 2) (Jardine and Sparks, 1984; Comans and Hockley, 1992) or molecular sites of differing reactivity such as high-reactivity inner-sphere complex sites and low-reactivity outer-sphere complex sites (Grossl et al., 1994, 1997).

However, it is unsound to conclude anything about mechanisms based solely on multiple rate constants that are calculated from multiple slopes of kinetic plots. There are other ways to definitively ascertain reaction mechanisms, such as calculating energies of activation, elucidating rate-limiting steps through stopped flow and interruption approaches, using independent or direct methods to determine mechanisms such as spectroscopic and microscopic techniques, and employing blocking agents that are specific for certain reaction sites. An example of the latter approach is found in the research of Jardine and Sparks (1984) who studied K–Ca exchange on a Delaware soil at three temperatures and observed two apparent simultaneous first-order reactions at 283 and 298 K (Figure 13.4). They hypothesized that the first, more rapid reaction was predominantly due to adsorption on external planar sites of the organic matter and kaolinite in the soil. The slower reaction was ascribed to vermiculitic clay sites that promoted slow pore and surface diffusion. These hypotheses were seemingly validated using a large organic polymer, cetyltrimethylammonium bromide (CTAB), which because of its size is sterically hindered from internal sites. Thus, CTAB should only block external planar sites. When CTAB was applied to the soil, the first slope was eliminated, while the second slope was still present, suggesting multireactive sites.

While first-order models have been used widely to describe the kinetics of CRs on natural materials, a number of other simple kinetic models have also been employed. These include various ordered equations such as zero, second, and fractional order;
FIGURE 13.4 First-order kinetics for potassium adsorption at three temperatures on Evesboro soil with inset showing the initial 50 min of the first-order plots at 298 and 313 K. (Reprinted from Jardine, P.M., and D.L. Sparks. 1984. Potassium-calcium exchange in a multireactive soil system. I. Kinetics. Soil Sci. Soc. Am. J. 48:39–45. Terms in equations are defined in the text of the chapter.

[a] Describing the reaction $A \rightarrow Y$.

[b] $\ln x = 2.303 \log x$ is the conversion from natural logarithms (ln) to base 10 logarithms (log).

Elovich; power function or fractional power; and parabolic diffusion models. A brief discussion of some of these will be given; the final forms of the equations are given in Table 13.1. For more complete details and applications of these models, one may consult Sparks (1989, 1995, 1998, 1999a, 1999b, 2002).

13.4.2 Elovich Equation

The Elovich equation was originally developed to describe the kinetics of heterogeneous chemisorption of gases on solid surfaces (Low, 1960). It seems to describe a number of reaction mechanisms including bulk and surface diffusion and activation and deactivation of catalytic surfaces.

In soil chemistry, the Elovich equation has been used to describe the kinetics of sorption and desorption of various inorganic materials on soils (Sparks, 1989, 1995, 1998, 1999a, 1999b, 2002). It can be expressed as (Chien and Clayton, 1980)

$$q = \left(\frac{1}{\beta}\right) \ln(\alpha\beta) + \left(\frac{1}{\beta}\right) \ln t, \tag{13.10}$$

where

　q is the amount of sorbate per unit mass of sorbent at time t
　α and β are constants during any one experiment

A plot of q versus $\ln t$ should give a linear relationship if the Elovich equation is applicable with a slope of $(1/\beta)$ and an intercept of $(1/\beta)\ln(\alpha\beta)$. An application of Equation 13.10 to P sorption on soils is shown in Figure 13.5.

Some investigators have used the α and β parameters from the Elovich equation to estimate reaction rates. For example, it has been suggested that a decrease in β and/or an increase in α would increase reaction rate. However, this is questionable. The slope of plots using Equation 13.10 changes with the concentration of the sorptive and with the solution-to-soil ratio (Sharpley, 1983). Therefore, the slopes are not always characteristic of the soil but may depend on various experimental conditions.

Some researchers also have suggested that breaks or multiple linear segments in Elovich plots could indicate a changeover
FIGURE 13.5 Plot of Elovich equation for phosphate sorption on two soils where C_0 is the initial phosphorus concentration in the soil solution at time t. The quantity (C_0-C) can be equated to q, the amount sorbed at time t. (Reprinted from Chien, S.H., and W.R. Clayton. 1980. Application of Elovich equation to the kinetics of phosphate release and sorption in soils. Soil Sci. Soc. Am. J. 44:265–268. With permission from the Soil Science Society of America.)

from one type of binding site to another (Atkinson et al., 1970). However, such mechanistic suggestions may not be correct (Sparks, 1989, 1995).

13.4.3 Parabolic Diffusion Equation

The parabolic diffusion equation is often used to suggest that diffusion-controlled phenomena are rate limiting. It was originally derived from radial diffusion in a cylinder where the ion concentration on the surface is constant, and initially, the ion concentration within the cylinder is uniform. It is also assumed that ion diffusion through the upper and lower faces of the cylinder is negligible. Following Crank (1976), the parabolic diffusion equation as applied to soils can be expressed as

$$\left(\frac{Q_t}{Q_\infty}\right) = \frac{4}{\pi^{1/2}}\frac{Dt^{1/2}}{r^2} - \frac{Dt}{r^2} - \frac{1}{3\pi^{1/2}}\frac{Dt^{3/2}}{r^2}, \quad (13.11)$$

where
  r is the radius of the cylinder
  Q_t is the quantity of diffusing substance that has left the cylinder at time t
  Q_∞ is the corresponding quantity after infinite time
  D is an apparent diffusion coefficient

For the relatively short times in most experiments, the third and subsequent terms may be ignored and thus

$$\frac{Q_t}{Q_\infty} = \frac{4}{\pi^{1/2}}\frac{Dt^{1/2}}{r^2} - \frac{Dt}{r^2}$$

or   (13.12)

$$\frac{1^c}{t}\frac{Q_t^m}{Q_\infty} = \frac{4}{\pi^{1/2}}\frac{Dt^{1/2}}{r^2}\frac{1}{t^{1/2}} - \frac{Dt}{r^2},$$

and thus, a plot of $Q_t/Q_\infty/t$ versus $1/t^{1/2}$ should give a straight line with a slope of

$$\frac{4}{\pi^{1/2}}\left(\frac{D}{r^2}\right)^{1/2}$$

and intercept of $-D/r^2$. Thus, if r is known, D may be calculated from both the slope and intercept.

The parabolic diffusion equation has successfully described metal reactions on soils and soil constituents (Chute and Quirk, 1967; Jardine and Sparks, 1984; Krishnamurti and Huang, 1992; Krishnamurti et al., 1997), feldspar weathering (Wollast, 1967), and pesticide reactions (Weber and Gould, 1966).

13.4.4 Fractional Power or Power Function Equation

This equation can be expressed as

$$q = kt^v, \quad (13.13)$$

where
  q is amount of sorbate per unit mass of sorbent at time t
  k and v are constants
  v is positive and <1

Equation 13.13 is empirical, except for the case where $v = 0.5$, when it is similar to the parabolic diffusion equation.

Equation 13.13 and various modified forms have been used by a number of researchers to describe the kinetics of reactions in natural materials (Kuo and Lotse, 1974; Havlin and Westfall, 1985).

13.4.5 $Z(t)$ and Diffusion Models

In a number of studies, several simple kinetic models have described rate data well, based on correlation coefficients and standard errors of the estimate (Chien and Clayton, 1980; Onken and Matheson, 1982; Sparks and Jardine, 1984; Allen et al., 1995). Despite this, there is often an inconsistent relation between the equation that gives the best fit and the physicochemical and mineralogical properties of the sorbent(s) being studied. Another problem with some of the kinetic models is that they are empirical and no meaningful rate parameters can be obtained.

Aharoni and Ungarish (1976) and Aharoni (1984) noted that some simple kinetic models are approximations of more general expressions within certain limited time ranges. They suggested a generalized empirical equation by examining the applicability of power function, Elovich, and first-order equations to experimental data. By writing these as the explicit functions of the reciprocal of the rate (Z), which is $(dq/dt)^{-1}$, one can show that a plot of Z versus t should be convex if the power function equation is operational (1 in Figure 13.6); linear if the Elovich
FIGURE 13.6 Plot of *Z* versus time implied by (1) power function model, (2) Elovich model, and (3) first-order model. The equations for the models were differentiated and expressed as explicit functions of the reciprocal of the rate, *Z*. (Reprinted with permission from Aharoni, C., and D.L. Sparks. 1991. Kinetics of soil chemical reactions: A theoretical treatment, p. 1–18. *In* D.L. Sparks and D.L. Suarez (eds.) Rates of soil chemical processes. SSSA, Madison, WI.)
FIGURE 13.7 Sorption of phosphate by a Typic Dystrochrept soil plotted as *Z* versus time. The circles represent the experimental data of Polyzopoulos et al. (1986). The solid line is a curve calculated according to a homogeneous diffusion model. (Reprinted with permission from Aharoni, C., and D.L. Sparks. 1991. Kinetics of soil chemical reactions: A theoretical treatment, p. 1–18. *In* D.L. Sparks and D.L. Suarez (eds.) Rates of soil chemical processes. SSSA, Madison, WI.)

equation is appropriate (2 in Figure 13.6); and concave if the first-order equation is appropriate (3 in Figure 13.6). However, such plots for soil systems (Figure 13.7) are usually S-shaped, convex at small, concave at large, and linear at some intermediate *t* value suggesting that the reaction rate can best be described by the power function, first order and Elovich equations in these ranges of *t*, respectively. Thus, the S-shaped curve indicates that the above equations may be applicable, each over some limited time range.

One of the reasons a particular kinetic model appears to be applicable may be that the study is conducted during the time range when the model is most appropriate. While sorption, for example, decreases over many orders of magnitude before equilibrium is approached, with most methods and experiments, only a portion of the entire reaction is measured, and over this time range, the assumptions associated with a simple kinetic model (power function, Elovich, and first order) are valid. Aharoni and Suzin (1982a, 1982b) showed that the S-shaped curves could be well described using homogeneous and heterogeneous diffusion models. In homogeneous diffusion situations, the final and initial portions of the S-shaped curves (conforming to the power function and first-order equations, respectively) predominated, whereas in instances where the heterogeneous diffusion model was operational, the linear portion of the S-shaped curve that conformed to the Elovich equation predominated. Derivations of homogeneous and heterogeneous diffusion models can be found in Aharoni and Sparks (1991).

13.4.6 Implications of Diffusion Models

The finding that slower reactions at the soil mineral/liquid interface can be described by diffusional models indicates that the kinetics of chemical processes cannot be considered separately from physically limited transport phenomena. Thus, such a combination of processes cannot be treated using first- or other-order chemical kinetic equations. When one states that a reaction between the molecular species *A* and *B* is first order with respect to *A*, one assumes that the molecules of *A* have equal chances of participating in the reaction, and therefore, the rate is proportional to the concentration (C_A). This reasoning can be extended to a reaction between a sorbing surface and a sorptive. In this case, C_A refers to the number of reactive sites per unit area, which corresponds to the number of unoccupied sites per unit area ($1 - \theta_A$). However, by using first-order kinetics (or other order kinetics), one tacitly assumes that all the surface sites are potential reactants at any time and have an opportunity of participating in the sorption process. If one assumes that there are sites that cannot be reached directly from the fluid phase, but can be reached after the sorbate has undergone sorption and desorption at other sites, one cannot separate chemical kinetics from diffusion-limited kinetics. The overall kinetic process obeys a diffusion equation since diffusion is the rate-limiting process. However, the diffusion coefficient, which reflects the rate at which the sorbate jumps from one site to another, is determined by the rate of the CRs by which the sorbent–sorbate bonds are created and destroyed. Additionally, the activation energy for diffusion is equivalent to the activation energy of the CR.

13.4.7 Multiple Site Models

Based on the previous discussion, it is evident that simple chemical kinetic models such as ordered reaction, power function, and Elovich models may not be appropriate to describe

reactions in heterogeneous systems such as soils, sediments, and soil components. In these systems where there is a range of particle sizes and multiple retention sites, both chemical kinetics and transport phenomena are occurring simultaneously, and a fast reaction is often followed by a slower reaction(s). In such systems, nonequilibrium models that describe both chemical and physical nonequilibrium and that consider multiple components and sites are more appropriate. Physical nonequilibrium is ascribed to some rate-limiting transport mechanism such as FD or PD, while chemical nonequilibrium is due to a rate-limiting mechanism at the particle surface (CR). Nonequilibrium models include two-site, multiple site, radial diffusion (pore diffusion), surface diffusion, and multiprocess models (Table 13.2). Emphasis here will be placed on the use of these models to describe sorption phenomena.

The term sites can have a number of meanings (Brusseau and Rao, 1989): (1) specific, molecular scale reaction sites; (2) sites of differing degrees of accessibility (external and internal);

(3) sites of differing sorbent type (organic matter and inorganic mineral surfaces); and (4) sites with different sorption mechanisms. With chemical nonequilibrium sorption processes, the sorbate may undergo two or more types of sorption reactions, one of which is rate limiting. For example, a metal cation may sorb to organic matter by one mechanism and to mineral surfaces by another mechanism, with one of the mechanisms being time dependent.

13.4.7.1 Chemical Nonequilibrium Models

Chemical nonequilibrium models describe time-dependent reactions at sorbent surfaces. The one-site model is a first-order approach that assumes that the reaction rate is limited by only one process or mechanism on a single class of sorbing sites and that all sites are of the time-dependent type. In many cases, this model appears to describe soil CRs quite well. However, often it does not. This model would seem not appropriate for most heterogeneous systems since multiple sorption sites exist.

TABLE 13.2 Comparison of Sorption Kinetic Models

Conceptual Model	Fitting Parameters	Model Limitations
One-site model k_d $S \rightarrow C$	k_d	Cannot describe biphasic sorption/desorption
Two-site model $K_p D_{eff}$ $S' \rightarrow C'_s \rightarrow C$	k_d, K_p, X_1	May not describe the "bleeding" or slow, reversible, nonequilibrium desorption for residual sorbed compounds (Karickhoff, 1980)
Radial diffusion penetration retardation (pore diffusion) model (Wu and Gschwend, 1986) $K_p D_{eff}$ $S' \leftrightarrow C' \rightarrow C$	$D_{eff} = f(n,t)D_m n/(1-n)\rho_s K_p$	Cannot describe instantaneous uptake without additional correction factor; did not describe kinetic data for times greater than 10^3 min (Wu and Gschwend, 1986)
Dual-resistance surface diffusion model (Miller and Pedit, 1992) $D_s k_b$ $S' \rightarrow C'_s \rightarrow C$	D_s, k_b	Model calibrated with sorption data predicted more desorption than occurred in the desorption experiments (Miller and Pedit, 1992)
Multisite continuum compartment model (Connaughton et al., 1993) $F(t) = 1 - \dfrac{M(t)}{M} = 1 - \left(\dfrac{\beta}{\beta+1}\right)^\alpha$	α, β	Assumption of homogeneous, spherical particles and diffusion only in aqueous phase
Pore space diffusion model (Fuller et al., 1993) $\left(\in + \dfrac{S_a}{n} K_s C(r)^{(1-1/n)}\right)\dfrac{\partial C(r)}{\partial t} = D_e\left(\dfrac{\partial^2 C(r)}{\partial r^2} + \dfrac{2\partial C(r)}{r\partial r}\right)$	$D_e, \in, K_s, 1/n, F_{eq}$	

Source: Partially adapted from Connaughton, D.F., J.R. Stedinger, L.W. Lion, and M.L. Shuler. 1993. Description of time-varying desorption kinetics: Release of naphthalene from contaminated soils. Environ. Sci. Technol. 27:2397–2403.

S, concentration of the bulk sorbed contaminant (g g^{-1}); C, concentration of the bulk aqueous-phase contaminant (g mL^{-1}); k_d, first-order desorption rate coefficient (min^{-1}); S_2, concentration of the sorbed contaminant that is rate limited (g g^{-1}); S_p concentration of the contaminant that is in equilibrium with the bulk aqueous concentration (g g^{-1}); X_1, fraction of the bulk sorbed contaminant that is in equilibrium with the aqueous concentration; K_p, sorption equilibrium partition coefficient (mL g^{-1}); D_{eff}, effective diffusivity of sorbate molecules or ions in the particles (cm^2 s^{-1}); S', concentration of contaminant in immobile bound state (mol g^{-1}); C', concentration of contaminant free in the pore fluid (mol cm^{-3}); n, porosity of the sorbent (cm^3 of fluid cm^{-3}); D_m, pore fluid diffusivity of the sorbate (cm^2 s^{-1}); ρ_s, specific gravity of the sorbent (g cm^{-3}); $f(n,t)$, pore geometry factor; k_b, boundary layer mass transfer coefficient (m s^{-1}); r, radius of the spherical solid particle, assumed constant (m); ρ, macroscopic particle density of the solid phase (g m^{-3}); C_s, solution-phase solute concentration corresponding to an equilibrium with the solid-phase solute concentration at the exterior of the particle (g L^{-1}); D_s, surface diffusion coefficient (m s^{-1}); K_p, can be determined independently; K_p, D_m, and ρ_s can be determined independently; $F(t)$, fraction of mass released through time t; $M(t)$, mass remaining after time t; M, total initial mass; β, scale parameter necessary for determination of mean and standard deviation of k_s; α, shape parameter; $\in$, internal porosity of sorbent; $C(r)$, concentration of sorptive in the aqueous phase in the pore fluid at radial distance r; S_a is the surface of sorbent per unit volume of solid; $1/n$, the adsorption isotherm slope; K_a, adsorption isotherm intercept; D_{eq}, effective diffusion coefficient; a, radius of the aggregate; F_{eq}, equilibrium fraction of absorption sites.

The two-site (two compartment, two box) or bicontinuum model has been widely used to describe chemical nonequilibrium (Leenheer and Ahlrichs, 1971; Hamaker and Thompson, 1972; Karickhoff, 1980; Karickhoff and Morris, 1985; McCall and Agin, 1985; Jardine et al., 1992) and physical nonequilibrium (Nkedi-Kizza et al., 1984; Lee et al., 1988; van Genuchten and Wagenet, 1989; Table 13.2). This model assumes that there are two reactions occurring, one that is fast and reaches equilibrium quickly and a slower reaction that can continue for long time periods. The reactions can occur either in series or in parallel (Brusseau and Rao, 1989).

In describing chemical nonequilibrium with the two-site model, two types of sorbent sites are assumed. One site involves an instantaneous equilibrium reaction and the other, the time-dependent reaction. The former is described by an equilibrium isotherm equation while a first-order equation is usually employed for the latter.

With the two-site model, there are two adjustable or fitting parameters: the fraction of sites at local equilibrium (X_1), and the rate constant (k). A distribution (K_d) or partition coefficient (K_p) is determined independently from a sorption/desorption isotherm.

To account for the multiple sites that may exist in heterogeneous systems, Connaughton et al. (1993) developed a multisite compartment (continuum) model (Γ) that incorporates a continuum of sites or compartments with a distribution of rate coefficients that can be described by a gamma density function. A fraction of the sorbed mass in each compartment is at equilibrium with a desorption rate coefficient or distribution coefficient for each compartment or site (Table 13.2). The multisite model has two fitting parameters α, a shape parameter, and $1/\beta$, which is a scale parameter that determines the mean standard deviation of the rate coefficients. Figure 13.8 shows application of the Γ model to desorption of naphthalene from contaminated soils. The entire desorption process was described well with this model.

13.4.7.2 Physical Nonequilibrium Models

A number of models can be used to describe physical nonequilibrium reactions. Since transport processes in the mobile phase are not usually rate limiting, physical nonequilibrium models focus on diffusion in the immobile phase or interaggregate/diffusion processes such as pore and/or surface diffusion. The transport between mobile and immobile regions is accounted for in physical nonequilibrium models in three ways (Brusseau and Rao, 1989): (1) explicitly with Fick's law to describe the physical mechanism of diffusive transfer, (2) explicitly by using an empirical first-order mass transfer expression to approximate solute transfer, and (3) implicitly by using an effective or lumped dispersion coefficient that includes the effects of sink/source differences and hydrodynamic dispersion and axial diffusion.

A pore diffusion model (Table 13.2) has been used by a number of investigators to study sorption processes using batch systems (Wu and Gschwend, 1986; Steinberg et al., 1987; Ball
FIGURE 13.8 Mass fractional release of naphthalene from two soils, S2 and S3 (S2 is a freshly contaminated soil, reacted with naphthalene for 3 months and S3 is a field [aged]-contaminated soil) fitted with a multisite continuum compartment (Γ) model. (Reprinted from Connaughton, D.F., J.R. Stedinger, L.W. Lion, and M.L. Shuler. 1993. Description of time-varying desorption kinetics: Release of naphthalene from contaminated soils. Environ. Sci. Technol. 27:2397–2403. With permission American Chemical Society.)

and Roberts, 1991; Harmon et al., 1992; Pignatello et al., 1993). Wu and Gschwend (1986) successfully used the pore diffusion model to describe chlorobenzene congener sorption/desorption on soils and sediments. Figure 13.9 shows experimental and model fits for tetrachlorobenzene and pentachlorobenzene
FIGURE 13.9 Experimental and model fitting results for pentachlorobenzene and tetrachlorobenzene sorption on Iowa soils where C is the dissolved concentration of organic chemical in the bulk solution, C_0 is the initial concentration, and C_e is the equilibrium concentration. The points represent experimental data and the solid lines represent fit of the data to the radial diffusion (pore diffusion) model. (Reprinted from Wu, S., and P.M. Gschwend. 1986. Sorption kinetics of hydrophobic organic compounds to natural sediments and soils. Environ. Sci. Technol. 20:717–725. With permission from American Chemical Society.)

sorption on soils. The sole fitting parameter in this model is the effective diffusion coefficient (D_e), which may be estimated a priori from chemical and colloidal properties. However, this estimation is only valid if the sorbent material has a narrow particle size distribution so that an accurate, average particle size can be defined. Moreover, in the pore diffusion model, an average representative D_e is assumed, which means there is a continuum in properties across an entire pore size spectrum. This is not a valid assumption for micropores in which there are higher adsorption energies of sorbates causing increased sorption. The increased sorption reduces diffusive transport rates and results in nonlinear isotherms for sorbents with pores less than several sorbate diameters in size. Other factors can cause reduced transport rates in micropores including steric hindrance, which increases as the pore size approaches the solute size and greatly increased surface area to pore volume ratios (which occurs as pore size decreases).

Another problem with the pore diffusion model is that sorption and desorption kinetics may have been measured over a narrow concentration range. This is a problem since a sorption/desorption mechanism in micropores at one concentration may be insignificant at another concentration.

Fuller et al. (1993) used a pore space diffusion model (Table 13.2) to describe arsenate adsorption on ferrihydrite that included a subset of sites whereby sorption was at equilibrium. A Freundlich model was used to describe sorption on these sites. Diffusion into the particle was described by Fick's second law of diffusion; homogeneous, spherical aggregates, and diffusion only in the aqueous phase were assumed. Figure 13.10 shows the fit of the model when sorption at all sites was controlled by intraaggregate diffusion. The fit was better when sites that had attained sorption equilibrium were included based on the assumption that there was an initial rapid sorption on external surface sites before intraaggregate diffusion.
FIGURE 13.10 Comparison of pore space diffusion model fits of As(V) sorption with experimental data (dashed curve represents sorption where all surface sites are diffusion limited and the solid curve represents sorption on equilibrium sites plus diffusion-limited sites). (Reprinted from Fuller, C.C., J.A. Davis, and G.A. Waychunas. 1993. Surface chemistry of ferrihydrite: Part 2. Kinetics of arsenate adsorption and coprecipitation. Geochim. Cosmochim. Acta 57:2271–2282. With permission from Elsevier.)

Pedit and Miller (1995) have developed a general multiple particle class pore diffusion model that accounts for differences in physical and sorptive properties for each particle class (Table 13.2). The model includes both instantaneous equilibrium sorption and time-dependent pore diffusion for each particle class. The pore diffusion portion of the model assumes that solute transfer between the intraparticle fluid and the solid phases is fast vis-à-vis interparticle pore diffusion processes.

Surface diffusion models, assuming a constant surface diffusion coefficient, have been used by a number of researchers (Weber and Miller, 1988; Miller and Pedit, 1992). The dual resistance model (Table 13.2) combines both pore and surface diffusion.

13.5 Kinetics of Important Reactions on Soils and Soil Components

In the past several decades, numerous studies have been conducted on the kinetics of metal, oxyanion, radionuclide, plant nutrient, and organic CRs on natural materials. In this section, emphasis will be placed on the kinetics of sorption/desorption, precipitation/dissolution, and oxidation/reduction reactions on soils and soil components.

13.5.1 Sorption/Desorption Reaction Rates

13.5.1.1 Heavy Metals and Oxyanions

CRs of heavy metals and metalloids on soil components are rapid, occurring on a millisecond timescale. For such rapid reactions, chemical techniques such as pressure jump (p-jump) relaxation (Hayes and Leckie, 1986; Sparks, 1989; Sparks and Zhang, 1991; Grossl and Sparks, 1995; Sparks et al., 1996) and molecular scale methods such as ATR–FTIR and QXAS (Parikh and Chorover, 2007; Ginder-Vogel et al., 2009; Landrot et al., 2010) should be used.

The use of p-jump relaxation to measure the kinetics of ion sorption/desorption on metal oxide surfaces was pioneered by several Japanese chemists. Their research includes some of the following sorption/desorption kinetic studies: divalent metal ion (Hachiya et al., 1984), phosphate (Mikami et al., 1983a), chromate (Mikami et al., 1983c), and uranyl (Mikami et al., 1983b) sorption reactions on γ-Al$_2$O$_3$. Hayes and Leckie (1986) were the first to use p-jump relaxation to study sorption/desorption kinetics of a metal ion contaminant (Pb^{2+}) on goethite (α-FeOOH). Other successive studies monitored the rapid sorption/desorption kinetics of molybdate (Zhang and Sparks, 1989), sulfate (Zhang and Sparks, 1990a), selenate and selenite (Zhang and Sparks, 1990b), Cu^{2+} (Grossl et al., 1994), and arsenate and chromate (Grossl et al., 1997) on goethite. Additional studies have investigated borate sorption/desorption kinetics on pyrophyllite (Keren et al., 1994) and on γ-Al$_2$O$_3$ (Toner and Sparks, 1995).

Details of many of these studies are summarized in Hayes and Leckie (1986), Sparks (1989, 1995), Sparks and Zhang (1991), and Sparks et al. (1996) and will not be detailed here. A study

of Grossl et al. (1997) will be summarized to illustrate rapid CR rates of two environmentally important oxyanions (chromate and arsenate) on goethite. A double relaxation was observed for both arsenate and chromate sorption/desorption over a pH range of 6.5–7.5 for arsenate and 5.5–6.5 for chromate, respectively (Figures 13.11 and 13.12). Based on the double relaxations, a two-step process, resulting in the formation of an inner-sphere bidentate surface complex (Figure 13.13) was proposed. The first step involves an initial ligand exchange reaction of the aqueous oxyanion (H_2AsO or $HCrO_4$) with goethite, forming an inner-sphere monodentate surface complex that produces signals associated with fast τ values. The succeeding step involves a second ligand exchange reaction, resulting in the formation of an inner-sphere bidentate surface complex that produces the signal associated with slow τ values.

To determine if the mechanism displayed in Figure 13.13 was plausible and consistent with the kinetic data, the following linearized rate equations relating reciprocal relaxation time values (τ^1) to the concentrations of reactive species were used:

$$\tau_{\text{fast}}^{-1} + \tau_{\text{slow}}^{-1} = k_1([\text{XOH}] + [\text{ion species}]) + k_{-1} + k_2 + k_{-2}, \quad (13.14)$$

$$\tau_{\text{fast}}^{-1} \cdot \tau_{\text{slow}}^{-1} = k_1[k_2 + k_{-2}]([\text{XOH}] + [\text{ion species}]) + k_1 k_{-2}, \quad (13.15)$$

where the ion species are H_2AsO_4 or $HCrO_4$. The derivation of these equations was obtained from Bernasconi (1976) and is based on the two-step reaction system (A + B $\leftrightarrow$ C $\leftrightarrow$ D). If the mechanism portrayed in Figure 13.13 is accurate, then a plot of $\tau_{\text{fast}}^1 + \tau_{\text{slow}}^{-1}$ and $\tau_{\text{fast}}^1 \cdot \tau_{\text{slow}}^{-1}$ as a function of the concentration term ([XOH] + [ion species]) should be linear. Plots of Equations 13.14 and 13.15 were linear for both arsenate and chromate, suggesting that the proposed mechanism was plausible (Figures 13.14 and 13.15).

Ainsworth. 1997. Arsenate and chromate retention mechanisms on goethite. 2. Kinetic evaluation using a pressure-jump relaxation technique. Environ. Sci. Technol. 31:321–326. Copyright American Chemical Society.)

From the plots in Figures 13.14 and 13.15, forward and reverse rate constants were obtained for the sorption and desorption reactions of both the monodentate and bidentate steps where k_1 = slope (Figure 13.14); k_{-1} = intercept (Figure 13.14) − slope (Figure 13.15)/slope (Figure 13.14); k_2 = intercept (Figure 13.14) − k_{-1} − k_{-2}; and k_{-2} = intercept (Figure 13.15)/k_{-1}. The calculated rate constants for both chromate and arsenate adsorption/desorption on goethite are listed in Table 13.3.

Overall, the forward rate constants associated with the formation of the inner-sphere oxyanion/goethite surface complexes were more rapid than the reverse rate constants. Therefore, the
FIGURE 13.14 Evaluation of the linearized rate Equation 13.14 for the mechanism displayed in Figure 13.13 for arsenate. (Reprinted from Grossl, P.R., M. Eick, D.L. Sparks, S. Goldberg, and C.C. Ainsworth. 1997. Arsenate and chromate retention mechanisms on goethite. 2. Kinetic evaluation using a pressure-jump relaxation technique. Environ. Sci. Technol. 31:321–326. rate-limiting steps were the reverse reactions. The equilibrium constants listed in Table 13.3 were calculated using the rate constants for each reaction step in the proposed mechanism (Figure 13.13) from the following relationship:

$$K_{eq} = \frac{k_1}{k_{-1}}. \tag{13.16}$$

The calculated equilibrium constant for Step 1 for arsenate was $10^{5.35}$ and for Step 2 was $10^{0.26}$, while the calculated K_{eq} for Step 1 for chromate was $10^{3.7}$ and for Step 2 was $10^{0.4}$. The sorption of both oxyanions and subsequent formation of inner-sphere surface complexes are thermodynamically favorable, with the exception of the equilibrium constant for the second step associated

TABLE 13.3 Calculated Rate Constants for Chromate and Arsenate Adsorption/Desorption on Goethite

	Step 1	Step 2
Arsenate	$k_1 = 10^{63}$ L mol^{-1} s^{-1}	$k_2 = 15\,s^{-1}$
	$k_{-1} = 8\,s^{-1}$	$k_{-2} = 8\,s^{-1}$
	$k_{eq} = 10^{5.35}$ L mol^{-1} s^{-1}	$k_{eq} = 10^{0.26}$
Chromate	$k_1 = 10^{5.8}$ L mol^{-1} s^{-1}	$k_2 = 16\,s^{-1}$
	$k_{-1} = 129\,s^{-1}$	$k_{-2} = 38\,s^{-1}$
	$k_{eq} = 10^{3.7}$ L mol^{-1} s^{-1}	$k_{eq} = 10^{-0.4}$

with chromate sorption (slightly less than 1). Thus, the monodentate chromate/goethite surface complex is slightly favored over the bidentate surface complex. This is in agreement with spectroscopic data obtained from x-ray absorption fine structure (XAFS) analyses (Fendorf et al., 1997), which indicate a mixture of both monodentate and bidentate arsenate, and chromate surface complexes; but at low-surface coverage, a greater proportion of chromate is associated with the monodentate complex than the bidentate complex. The results from both kinetic and XAFS experiments suggest that arsenate is more likely to form an inner-sphere surface complex with goethite than chromate.

While p-jump relaxation techniques are useful for measuring rapid reaction rates on soil components, the rate constants are calculated from linearized rate equations, which include parameters that are determined from equilibrium and modeling studies. Consequently, the rate "constants" are not directly determined.

The ideal way to measure rapid reaction rates that may often comprise a major portion of the total reaction process for many soil chemical processes, particularly on soil components is to use real-time molecular scale techniques such as ATR–FTIR and QXAS. With these techniques, one can not only measure reaction rates on millisecond timescales but also at the same time couple these measurements with spectroscopic analyses of the reaction mechanism (Parikh et al., 2008; Ginder-Vogel et al., 2009; Landrot et al., 2010).

While the initial sorption of heavy metals is rapid, with the CR step occurring on second or millisecond timescales, further sorption may be slow (Figure 13.16) occurring over timescales of days and longer. Such behavior has been observed for some Fe oxides. This slow sorption has been ascribed to several mechanisms, including interparticle or intraparticle diffusion in pores and solids, sites of low reactivity, and surface precipitation/nucleation (Sparks, 1998; Strawn and Sparks, 2000). With heterogeneous soils and even soil components, there may be a continuum between the three sorption mechanisms, for example, between adsorption and surface precipitation/nucleation. While it has generally been assumed that adsorption in comparison with surface precipitation/nucleation is much more rapid, recent
FIGURE 13.16 Kinetics of Ni sorption [%] on pyrophyllite (■), kaolinite (△), gibbsite (▲), and montmorillonite (○) from a 3 mM Ni solution at pH = 7.5 and an ionic strength $I = 0.1$M (NaNO$_3$). The last sample of each experiment was collected and analyzed by XAFS. (Reprinted from Scheidegger, A.M., G.M. Lamble, and D.L. Sparks. 1997. Spectroscopic evidence for the formation of mixed-cation hydroxide phases upon metal sorption on clays and aluminum oxides. J. Colloid Interface Sci. 186:118–128. With permission from Elsevier.)

studies (Scheidegger et al., 1998) that will be discussed later, have shown that surface precipitation/nucleation processes can occur on timescales as short as 15 min, which indicates that sorption and nucleation processes can occur simultaneously. However, in some cases, depending on reaction conditions and the metal involved, a particular sorption mechanism can dominate.

Obviously, an important factor affecting the degree of slow sorption/desorption of metals (and for that matter also of organic chemicals) is the time period the sorbate has been in contact with the sorbent (residence time). Bruemmer et al. (1988) studied Ni^{2+}, Zn^{2+}, and Cd^{2+} sorption on goethite, a porous Fe oxide that has defect structures in which metals can be incorporated to satisfy charge imbalances. Bruemmer et al. (1988) found, at pH 6, that as reaction time increased from 2 h to 42 days (at 293 K), adsorbed Ni^{2+} increased from 12% to 70% of total adsorption, and total Zn^{2+} and Cd^{2+} adsorption over this time increased by 33% and 21%, respectively. The kinetic reactions could be well described using a Fickian diffusion model. Metal uptake was hypothesized to occur by a three-step mechanism: (1) adsorption of metals on external surfaces, (2) solid-state diffusion of metals from external to internal sites, and (3) metal binding and fixation at positions inside the goethite particle.

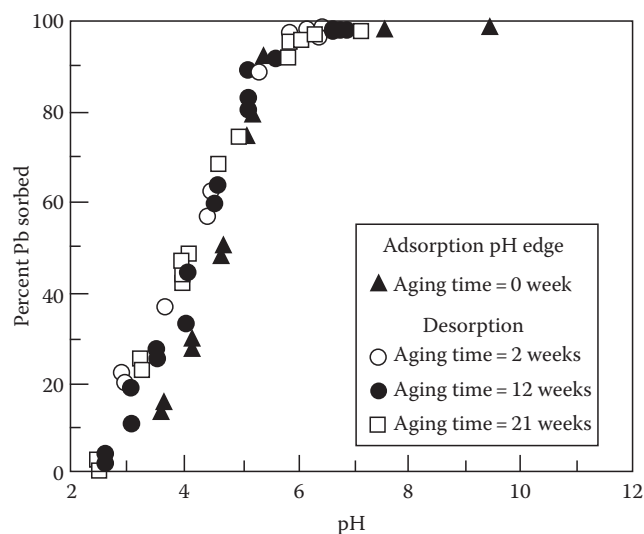
Ainsworth et al. (1994) studied the adsorption/desorption of Co^{2+}, Cd^{2+}, and Pb^{2b+} on hydrous Fe(III) as a function of aging and metal oxide residence time. Oxide aging did not cause hysteresis of metal cation sorption/desorption. Aging the oxide with the metal cations resulted in hysteresis with Cd^{2+} and Co^{2+} but little with


FIGURE 13.17 Fractional sorption–desorption of Pb^{2+} to hydrous Fe(III) as a function of pH and HFO–Pb^{2+} aging time. (Reprinted from Ainsworth, C.C., J.L. Pilon, P.L. Gassman, and W.G. Van Der Sluys. 1994. Cobalt, cadmium, and lead sorption to hydrous iron oxide: Residence time effect. Soil Sci. Soc. Am. J. 58:1615–1623. With permission from the Soil Science Society of America.)

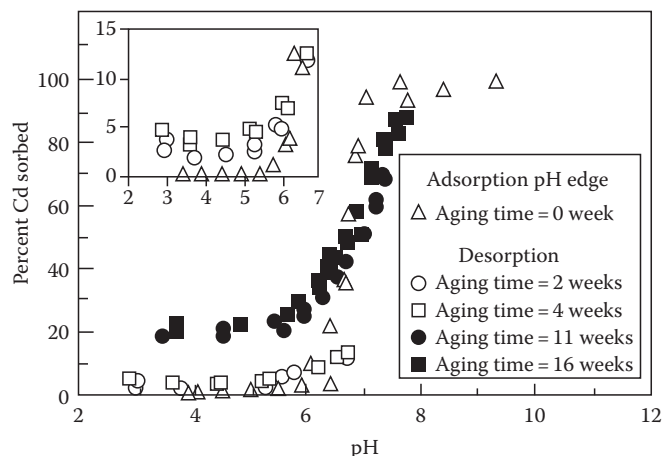
Pb^{2+}. With Pb^{2+} between pH 3 and 5.5 there was slight hysteresis over a 21 week aging process (hysteresis varied from <2% difference between sorption and desorption to ~10%). At pH 2.5, Pb^{2+} desorption was complete within a 16 h period and was not affected by aging time (Figure 13.17). However, with Cd^{2+} and Co^{2+}, extensive hysteresis was observed over a 16 week aging period and the hysteresis increased with aging time (Figures 13.18 and 13.19). After 16 weeks of aging, 20% of the Cd^{2+} and 53% of the Co^{2+} were not desorbed, and even at pH 2.5, hysteresis was observed. The extent


FIGURE 13.18 Fractional sorption–desorption of Cd^{2+} to hydrous Fe oxide (HFO) as a function of pH and HFO–Cd^{2+} aging time; insert shows adsorption–desorption of Cd^{2+} to HFO at 2 and 4 week aging times. (Reprinted from Ainsworth, C.C., J.L. Pilon, P.L. Gassman, and W.G. Van Der Sluys. 1994. Cobalt, cadmium, and lead sorption to hydrous iron oxide: Residence time effect. Soil Sci. Soc. Am. J. 58:1615–1623. With permission from the Soil Science Society of America.)
FIGURE 13.19 Fractional adsorption of Co^{2+} to hydrous Fe oxide (HFO) as a function of pH and HFO–Co^{2+} aging time. (Reprinted from Ainsworth, C.C., J.L. Pilon, P.L. Gassman, and W.G. of reversibility with aging for Co^{2+}, Cd^{2+}, and Pb^{2+} was inversely proportional to the ionic radius of the ions, namely, $Co^{2+} < Cd^{2+} < Pb^{2+}$. Ainsworth et al. (1994) attributed the hysteresis to Co and Cd incorporation into a recrystallizing solid (probably goethite) by isomorphic substitution and not to micropore diffusion.

Strawn and Sparks (2000) investigated the role that residence time and organic matter content had on Pb desorption kinetics from a Matapeake soil. Residence time had little effect on the amount of Pb desorbed, but marked hysteresis was observed at all residence times, which was ascribed to diffusion of Pb into the organic matter and strong metal–soil complexes.

Fuller et al. (1993) combined kinetic sorption and desorption experiments with spectroscopic observations (Waychunas et al., 1993) to study As sorption on ferrihydrite. Using XAFS spectroscopy, they found that As was sorbed predominantly as inner-sphere bidentate complexes, regardless of whether the As was adsorbed after the mineralization of the ferrihydrite or it was present during precipitation. No As surface precipitates were observed. Slow As sorption and desorption were explained as slow diffusion of the As to or from interior surface complexation sites that exist within disordered aggregates of crystallites. The kinetic reactions could be described using a Fickian diffusion model.

Slow metal sorption/desorption has also been ascribed to conversion of the metal sorbate from a high- to a low-energy state (Kuo and Mikkelsen, 1980; Padmanabham, 1983; Schultz et al., 1987; Backes et al., 1995). Lehmann and Harter (1984) measured the kinetics of chelate-promoted Cu^{2+} release from a soil to assess the strength of the bond formed. Sorption/desorption was biphasic, which was attributed to high- and low-energy bonding sites.

With increased residence time from 30 min to 24 h, Lehmann and Harter(1984) speculated that there was a transition of Cu from low to higher energy sites (as evaluated by release kinetics). Incubations for up to 4 days showed a continued uptake of Cu and a decrease in the fraction released within the first 3 min, which was referred to as the low-energy sorbed fraction.

Recent studies particularly using surface spectroscopic and microscopic techniques such as XAS and transmission electron microscopy (TEM) have shown that the formation of polynuclear surface species (e.g., surface precipitates) on natural materials such as clay minerals, metal oxides, and in soils is an important sorption and sequestration mechanism (Charlet and Manceau, 1993; Fendorf et al., 1994; Junta and Hochella, 1994; O'Day et al., 1994a, 1994b; Wersin et al., 1994; Scheidegger et al., 1996, 1997, 1998; Towle et al., 1997; Xia et al., 1997; Elzinga and Sparks, 1999; Roberts et al., 1999; Thompson et al., 1999a, 1999b; Ford and Sparks, 2000; Nachtegaal et al., 2005; McNear et al., 2007).

The surface precipitates of Co, Cr(III), Cu, and Ni on metal oxides and clay minerals have been observed at metal surface loadings far below a theoretical monolayer coverage and in a pH range well below the pH where the formation of metal hydroxide precipitates would be expected according to the thermodynamic solubility product. In Al-bearing soil components, the precipitates are mixed metal–Al hydroxide phases of the layered double hydroxide type. Recent studies using microfocused x-ray fluorescence (micro-XRF) and x-ray absorption spectroscopy (micro-XAS) have shown that Zn–Al layered double hydroxides (LDH) (Nachtegaal et al., 2005) and Ni–Al hydroxide LDH (McNear et al., 2007) precipitates occur in field-contaminated soils.

In general, the formation of surface precipitates has been considered a slow phenomenon. However, Scheidegger et al. (1998) have demonstrated that the rate of surface precipitate formation can be quite rapid. The appearance of surface precipitates during sorption of Ni to pyrophyllite at pH 7.5 occurred over time scales less than 1 h. Similar results were observed for Ni sorption to kaolinite. However, the kinetics of Ni sorption onto gibbsite, and subsequent surface precipitate formation, were slower than for pyrophyllite (Figures 13.16 and 13.20). Time-resolved XAFS studies demonstrated continued growth of the surface precipitate during Ni uptake as the structure and Ni:Al stoichiometry of the sorption complex approached that of a takovite-like phase (Scheidegger et al., 1998).

13.5.1.2 Organic Contaminants

Numerous studies on the kinetics of organic chemical sorption/desorption reactions on soils and soil components have shown that sorption/desorption is characterized by a rapid, reversible stage followed by a much slower, nonreversible stage (Karickhoff et al., 1979; DiToro and Horzempa, 1982; Karickhoff and Morris, 1985; Kan et al., 1997; Xing and Pignatello, 2005), or biphasic kinetics. The rapid phase has been ascribed to retention of the organic chemical in a labile form that is easily desorbed. However, the much slower reaction phase involves the entrapment of the chemical in a nonlabile form that is difficult to desorb. The labile form of the
FIGURE 13.20 Radial structure functions for Ni sorption to gibbsite for reaction times up to 620h demonstrating the appearance and growth of second shell contributions due to surface precipitation and growth of a hydrotalcite-like phase. (Reprinted from Scheidegger, A.M., D.G. Strawn, G.M. Lamble, and D.L. Sparks. 1998. The kinetics of mixed Ni–Al hydroxide formation on clay and aluminum oxide minerals: A time-resolved XAFS study. Geochim. Cosmochim. Acta 62:2233–2245. With permission from Elsevier.)

chemical is available for microbial attack, while the nonlabile portion is resistant to biodegradation.

This slower sorption/desorption reaction has been ascribed to intraparticle and interparticle diffusion of the chemical into soil organic matter (SOM) and inorganic soil components (Wu and Gschwend, 1986; Steinberg et al., 1987; Ball and Roberts, 1991).

Theories proposed by a number of researchers (Weber and Huang, 1996; Xing and Pignatello, 1997; Pignatello, 2000) have explained the slow diffusion of organic chemicals into SOM by considering SOM as a combination of "rubbery" and "glassy" polymers. The rubber-like phases are characterized by an expanded, flexible, and highly solvated structure with pores of subnanometer dimensions (holes) (Xing and Pignatello, 1997; Pignatello, 1998, 2000). Sorption in the rubbery phases results in linear, noncompetitive, and reversible behavior. The glassy phases have pores that are of subnanometer size, and sorption in this phase is characterized by nonlinearity and is competitive (Xing and Pignatello, 1997). These theories, relating slow diffusion into organic matter to diffusion in polymers, are somewhat validated in some studies measuring energies of activation (E_a) for organic chemical sorption. Cornelissen et al. (1997) studied the temperature dependence of slow adsorption and desorption kinetics of some chlorobenzenes, polychlorinated biphenyls (PCBs), and polycyclic aromatic hydrocarbons (PAHs) in laboratory- and field-contaminated sediments and obtained E_a values of 60–70kJ mol^{-1}, which are in the range for diffusion in polymers. These values are much higher than those for pore diffusion (20–40kJ mol^{-1}) suggesting that intraorganic matter diffusion may be a more important mechanism for slow organic chemical sorption than interparticle pore diffusion.

However, Chang et al. (1997) who studied sorption of toluene (TOL), *n*-hexane, and acetone on pressed humic acid disks found an insignificant amount of irreversibly bound residue with activation energies in the range of 42.3–65.8kJ mol^{-1}, suggesting a physical sorption process with little diffusion.

An example of the biphasic kinetics that is observed for many organic CRs in soils/sediments is shown in Figure 13.21. In this study, 55% of the labile PCB was desorbed from sediments in
FIGURE 13.21 (a) Short-term polychlorinated biphenyl (PCB) desorption in hours (h) from Hudson River sediment contaminated with 25 mg kg^{-1} PCB. Distribution of the PCB between the sediment (v) and XAD-4 resin (o) as well as the overall mass balance (D) is shown. The resin acts as a sink to retain the PCB that is desorbed (Carroll et al., 1994). (b) Long-term PCB desorption in months (mo) from Hudson River sediment contaminated with 25 mg kg^{-1} PCB. Distribution of the PCB between the sediment (■) and XAD-4 resin (●) is shown. The line represents a nonlinear regression of the data by a two-site model. (Reprinted from Carroll, K.M., M.R. Harkness, A.A. Bracco, R.R. Balcarcel. 1994. Application of a permeant/polymer diffusional model to the desorption of polychlorinated biphenyls from Hudson River sediments. Environ. Sci. Technol. 28:253–258. With permission from American Chemical Society.)

a 24 h period, while little of the remaining 45% nonlabile fraction was desorbed in 170 h (Figure 13.21a). Over another 1 year period, ~50% of the remaining nonlabile fraction desorbed (Figure 13.21b).

Pavlostathis and Mathavan (1992) observed a biphasic desorption process for field soils contaminated with trichloroethylene (TCE), tetrachloroethylene (PCE), TOL, and xylene (XYL). A fast desorption reaction occurred in 24 h followed by a much slower desorption reaction beyond 24 h. In 24 h, 9%–29%, 14%–48%, 9%–40%, and 4%–37% of the TCE, PCE, TOL, and XYL, respectively, were released. However, the apparent irreversibility or hysteresis may be an artifact caused by not reaching a true sorption equilibrium. For example, DiVincenzo and Sparks (1997), studying pentachlorophenol sorption/desorption on a soil, found that if desorption was initiated after an apparent sorption equilibrium (i.e., slow sorption was measured) was reached, hysteresis or irreversibility was significantly reduced.

A number of studies have also shown that with aging the nonlabile portion of the organic chemical in the soil/sediment becomes more resistant to release (McCall and Agin, 1985; Steinberg et al., 1987; Pignatello and Huang, 1991; Pavlostathis and Mathavan, 1992; Scribner et al., 1992; Alexander, 1995; Loehr and Webster, 1996). However, Connaughton et al. (1993) did not observe the nonlabile fraction increasing with age for naphthalene-contaminated soils.

One way to gauge the effect of time on organic contaminant retention in soils is to compare K_d (sorption distribution coefficient) values for freshly aged and aged soil samples. In most studies, K_d values are measured based on a 24 h equilibration between the soil and the organic chemical. When these values are compared to K_d values for field soils previously reacted with the organic chemical (aged samples), the latter have much higher K_d values, indicating that much more of the organic chemical is in a sorbed state. For example, Pignatello and Huang (1991) measured K_d values in freshly aged (K_d) and "aged" soils (K_{app}, apparent sorption distribution coefficient) reacted with atrazine and metolachlor, two widely used herbicides. The aged soils had been treated with the herbicides 15–62 months before sampling. The K_{app} values ranged from 2.3 to 42 times higher than the K_d values (Table 13.4).

Scribner et al. (1992) studying simazine (a widely used triazine herbicide for broadleaf and grass control in crops) desorption and bioavailability in aged soils found that K_{app} values were 15 times higher than K_d values. Scribner et al. (1992) also showed that 48% of the simazine added to the freshly aged soils was biodegradable over a 34-day incubation period while none of the simazine in the aged soil was biodegraded.

One of the implications of these results is that while many transport and degradation models for organic contaminants in soils and waters assume that the sorption process is an equilibrium process, the above studies clearly show that kinetic reactions must be considered when making predictions about the mobility and fate of organic chemicals. Moreover, calculation of K_d values based on a 24 h equilibration period, which are commonly used in fate and risk assessment models, can be

TABLE 13.4 Sorption Distribution Coefficients for Herbicides in Freshly Aged and Aged Soils

Herbicide	Soil	K_d (L kg^{-1})[a]	K_{app} (L kg^{-1})[b]

inaccurate since 24 h K_d values often overestimate the amount of organic chemical in the solution phase.

The finding that many organic chemicals are quite persistent in the soil environment has both good and bad features. The beneficial aspect is that the organic chemicals are less mobile and may not be readily transported in groundwater supplies. The negative aspect is that their persistence and inaccessibility to microbes may make decontamination more difficult, particularly if in situ remediation techniques such as biodegradation are employed.

13.5.2 Kinetics of Mineral Dissolution

13.5.2.1 Rate-Limiting Steps

Dissolution of minerals involves several steps (Stumm and Wollast, 1990): (1) mass transfer of dissolved reactants from the bulk solution to the mineral surface, (2) adsorption of solutes, (3) interlattice transfer of reaction species, (4) surface CRs, (5) removal of reactants from the surface, and (6) mass transfer of products into the bulk solution. Under field conditions, mineral dissolution is slow and mass transfer of reactants or products in the aqueous phase (Steps 1 and 6) is not rate limiting. Thus, the rate-limiting steps are either transport of reactants and products in the solid phase (Step 3) or surface CRs (Step 4) and removal of reactants from the surface (Step 5).

Transport-controlled dissolution reactions or those controlled by mass transfer or diffusion can be described using a parabolic rate law given later (Stumm and Wollast, 1990):

$$r = \frac{dC}{dt} = kt^{-1/2}, \qquad (13.17)$$

where

r is the reaction rate
C is the concentration in solution
t is time
k is the reaction rate constant

Integrating, C increases with $t^{1/2}$,

$$C = C_0 + 2kt^{1/2}, \qquad (13.18)$$

where C_0 is the initial concentration in solution.

If the surface reactions are slow compared to the transport reactions, dissolution is surface controlled, which is the case for most dissolution reactions of silicates and oxides. In surface-controlled reactions, the concentrations of solutes next to the surface are equal to the bulk solution concentrations and the dissolution kinetics are zero order if steady-state conditions are operational on the surface. Thus, the dissolution rate (r) is

$$r = \frac{dC}{dt} = kA, \qquad (13.19)$$

and r is proportional to the mineral's surface area, A. Thus, for a surface-controlled reaction, the relationship between t and C should be linear. Figure 13.22 compares transport- and surface-controlled dissolution mechanisms.

Intense arguments have ensued over the years concerning the mechanism for mineral dissolution. Those that supported a transport-controlled mechanism believed that a leached layer formed as mineral dissolution proceeded and that subsequent dissolution took place by diffusion through the leached layer (Wollast, 1967; Petrovic et al., 1976). Advocates of this theory found that dissolution was described by the parabolic rate law (Equation 13.18). However, the apparent transport-controlled kinetics may be an artifact caused by dissolution of hyperfine particles formed on the mineral surfaces after grinding that are highly reactive sites or by the use of batch methods that cause reaction products to accumulate causing precipitation of secondary minerals. These experimental artifacts can cause incongruent reactions and pseudoparabolic kinetics. Studies employing x-ray photoelectron spectroscopy (XPS) and nuclear resonance profiling (Schott and Petit, 1987; Casey et al., 1989) have demonstrated
FIGURE 13.22 (a) Transport- versus (b) surface-controlled dissolution. Schematic representation of concentration in solution, C, as a function of distance from the surface of the dissolving mineral. In the lower part of the figure, the change in concentration is given as a function of time. (Reprinted with permission from Stumm, W. 1992. Chemistry of the solid–water interface. Wiley, New York.)
FIGURE 13.23 Linear dissolution kinetics observed for the dissolution of γ-Al$_2$O$_3$. Representative of processes whose rates are controlled by a surface reaction and not by transport. (Reprinted from Furrer, G., and W. Stumm. 1986. The coordination chemistry of weathering. I. Dissolution kinetics of γ-Al$_2$O$_3$ and BeO. Geochim. Cosmochim. Acta 50:1847–1860. Copyright 1986. With permission from Elsevier.)

that although some incongruency may occur in the initial dissolution process, which may be diffusion controlled, the overall reaction is surface controlled. Energies of activation from 60 to 86 kJ mol^{-1} have been observed for dissolution of oxides and silicates, further suggesting surface-controlled dissolution (Lasaga, 1984; Jordan and Rammensee, 1996). An illustration of the surface-controlled dissolution of γ-Al$_2$O$_3$ resulting in a linear release of Al^{3+} with time is shown in Figure 13.23. The dissolution rate (r) can be obtained from the slope of Figure 13.23.

Scanning force microscopy (SFM), which has also been used increasingly as an in situ technique for imaging mineral surfaces immersed in aqueous solution during the course of dissolution (Hellman et al., 1992; Hillner et al., 1992a, 1992b; Johnsson et al., 1992; Bosbach and Rammensee, 1994; Maurice et al., 1995), permits a direct measure of surface-controlled dissolution rates by providing 3D data on changes in microtopography. In situ SFM has the unique ability to detect separate processes, such as dissolution and secondary phase formation, occurring simultaneously on a mineral surface (Maurice, 1998).

13.5.2.2 Surface-Controlled Dissolution Mechanisms

Dissolution of oxide minerals through a surface-controlled reaction by ligand- and proton-promoted processes has been described by Furrer and Stumm (1986), Zinder et al. (1986), and Stumm and Furrer (1987) using a surface coordination approach. The important reactants in these processes are H$_2$O, H$^+$, OH, ligands, and reductants and oxidants. The reaction mechanism occurs in two steps (Stumm and Wollast, 1990):

$$\text{Surface sites} + \text{reactants}\,(\text{H}^+, \text{OH}^-, \text{ligands}) \xrightarrow{\text{fast}} \text{surface species},$$

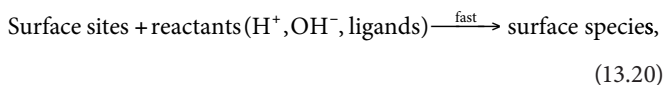
$$(13.20)$$


FIGURE 13.24 The dependence of surface reactivity and of kinetic mechanisms on the coordinative environment of the surface groups. (Reprinted from Stumm, W., and R. Wollast. 1990. Coordination chemistry of weathering. Kinetics of the surface-controlled dissolution of oxide minerals. Rev. Geophys. 28:53–69. With permission from American Geophysical Union.)

$$\text{Surface species} \xrightarrow[\text{detachment of metal(M)}]{\text{slow}} \text{M(aq).} \qquad (13.21)$$
Thus, the attachment of the reactants to the surface sites is fast, and detachment of metal species from the surface into solution is slow and rate limiting.

13.5.2.3 Ligand-Promoted Dissolution

Figure 13.24 shows how the surface chemistry of the mineral affects dissolution. One sees that surface protonation of the surface ligand increases dissolution by polarizing interatomic bonds close to the central surface ions that promote the release of a cation surface group into solution. Hydroxyls that bind to surface groups at higher pHs can ease the release of an anionic surface group into the solution phase.

Ligands that form surface complexes by ligand exchange with a surface hydroxyl add negative charge to the Lewis acid center coordination sphere and lower the Lewis acid acidity. This polarizes the M–O bonds causing detachment of the metal cation into the solution phase. Thus, inner-sphere surface complexation plays an important role in mineral dissolution. Ligands such as oxalate, salicylate, F^-, EDTA, and NTA increase dissolution, but others, such as SO_4^{2-}, CrO_4^{2-}, and benzoate, inhibit dissolution. Phosphate, arsenate, and selenite enhance dissolution at low pH, and dissolution is inhibited at pH > 7 (Bondietti et al., 1993).

The reason for these differences may be that bidentate species that are mononuclear promote dissolution while binuclear bidentate species inhibit dissolution. With binuclear bidentate complexes, more energy may be needed to remove two central atoms from the crystal structure. With phosphate and arsenate, at low pH, mononuclear species are formed while at higher pH (~pH 7), binuclear or trinuclear surface complexes form. Mononuclear bidentate complexes are formed with oxalate while binuclear bidentate complexes form with CrO_4^{2-}. Additionally, the electron donor properties of CrO_4^{2-} and oxalate are also different. With CrO_4^{2-}, a high redox potential is maintained at the oxide surface, which restricts reductive dissolution (Stumm and Wollast, 1990; Stumm, 1992). Dissolution can also be inhibited by cations such as VO^{2+}, Cr(III), and Al(III) that block surface functional groups (Bondietti et al., 1993).

One can express the rate of the ligand-promoted dissolution (R_L) as

$$R_L = k_L' (\equiv ML) = k_L' C_L^s, \qquad (13.22)$$

where

k_L' is the rate constant for ligand-promoted dissolution (t^{-1})
ML is the metal–ligand complex
C_L^s is the surface concentration of the ligand (mol m^{-2})

Equation 13.22 adequately describes ligand-promoted dissolution of γ-Al$_2$O$_3$ (Figure 13.25).
FIGURE 13.25 The rate of ligand catalyzed dissolution of γ-Al$_2$O$_3$ by the aliphatic ligands oxalate, malonate, and succinate, R_L (nmol m^{-2} h^{-1}), can be interpreted as a linear dependence on the surface concentrations of the ligand complexes, C_L^s. In each case, the individual values for C_L^s were determined experimentally. (Reprinted from Furrer, G., and W. Stumm. 1986. The coordination chemistry of weathering. I. Dissolution kinetics of γ-Al$_2$O$_3$ and BeO. Geochim. Cosmochim. Acta 50:1847–1860. With permission from Elsevier.)

13.5.2.4 Proton-Promoted Dissolution

Under acid conditions, protons can promote mineral dissolution by binding to surface oxide ions, causing bonds to weaken which is followed by detachment of metal species into solution. The proton-promoted dissolution rate (R_H) can be expressed as (Stumm and Wollast, 1990)

$$R_H = k_H'(\equiv MOH_2^+)^j = k_H'(C_H^s)^j, \qquad (13.23)$$

where

k_H' is the rate constant for proton-promoted dissolution
MOH_2^+ is the metal–proton complex
C_H^s is the concentration of the surface-adsorbed proton complex (mol^{-2})
j corresponds to the oxidation state of the central metal ion in the oxide structure (i.e., $j = 3$ for Al(III) and Fe(III) in simple cases)

If dissolution occurs by only one mechanism, j is an integer. Figure 13.26 shows an application of Equation 13.23 for the proton-promoted dissolution of γ-Al$_2$O$_3$.

13.5.2.5 Overall Dissolution Mechanisms

The rate of mineral dissolution, which is the sum of the ligand, proton, and deprotonation-promoted (or bonding of OH ligands) dissociation [$R_{OH} = k_{OH}'(C_{OH}^s)^i$] rates along with the pH-independent portion of the dissolution rate (k_{H_2O}'), which is due to hydration, can be expressed as (Stumm and Wollast, 1990)
FIGURE 13.26 The dependence of the rate of proton-promoted dissolution of γ-Al$_2$O$_3$, R_H (mol m^{-2} h^{-1}) on the surface concentration of the proton complexes, C_H^s (mol m^{-2}). (Reprinted from Furrer, G., and W. Stumm. 1986. The coordination chemistry of weathering. I. Dissolution kinetics of γ-Al$_2$O$_3$ and BeO. Geochim. Cosmochim. Acta 50:1847–1860. With permission of Elsevier Science, Amsterdam, the Netherlands.)

$$R = k_L'(C_L^s) + k_H'(C_H^s)^j + k_{OH}'(C_{OH}^s)^i + k_{H_2O}'. \qquad (13.24)$$

Equation 13.24 is valid if dissolution occurs in parallel at varying metal centers (Furrer and Stumm, 1986).

13.5.2.6 Dissolution Kinetics of Metal Hydroxide Precipitates

The formation of metal hydroxide surface precipitates appears to be an important way to sequester metals. As the surface precipitates age, metal dissolution is greatly reduced (Figure 13.27). Thus, the metals are less prone to leaching and being taken up by plants and microbes. Peltier et al. (2010) reacted two soils of varying mineralogy and organic matter content with 3 mM Ni at two pHs, 6 and 7.5, and evaluated Ni bioavailability using a biosensor. At pH 6, where surface precipitates did not form, 60% of the Ni was bioavailable. However, at pH 7.5, where precipitates were observed to form from XAFS analyses, Ni bioavailability was markedly reduced to 25%. Similar results were found by Everhart et al. (2006).

The decrease in metal release and bioavailability is linked to the increasing silication of the interlayer of the LDH phases with increased residence time, resulting in a mineral transformation from a LDH phase to a precursor phyllosilicate surface precipitate (Ford et al., 1999; Ford and Sparks, 2000). The mechanism for this transformation is thought to be due to diffusion of Si, originating from weathering of the sorbent, into the interlayer space
FIGURE 13.27 Kinetics of Ni detachment from surface precipitates at pH = 4. Relative Ni remaining on the surface (%) is shown for the *conventional method* (O) and the *replenishment method* (■) as a function of the reaction time. Ninety-eight percent of the initial Ni was sorbed in the beginning of the detachment experiment. The dissolution of an equivalent amount of crystalline Ni(OH)$_2$ (in mol) at pH = 4 is given for comparison (▲). (Reprinted from Scheidegger, A.M., and D.L. Sparks. 1996a. Kinetics of the formation and the dissolution of nickel surface precipitates on pyrophyllite. Chem. Geol. 132:157–164. With permission of Elsevier Science, Amsterdam, the Netherlands.)

of the LDH, replacing the anions such as NO$_3$. Polymerization and condensation of the interlayer Si slowly transform the LDH into a precursor metal–Al phyllosilicate. The metal stabilization that occurs in surface precipitates on Al-free sorbents (e.g., talc) may be due to Ostwald ripening, resulting in increased crystallization; however, microscopic analyses have shown that Ni–Al LDH phases appear to be amorphous (Livi et al., 2009). Peltier et al. (2006), using acid-solution calorimetry and results from previous calorimetry studies, showed that the enthalpy of formation of LDH phases is more exothermic, indicating great stability, on the order of Cl < NO$_3$ < SO$_4$ < CO$_3$ < Si of interlayer anionic composition, and that LDH phases were much more stable than a Ni(OH)$_2$ phase.

13.5.3 Redox Kinetics

It is well known that Mn(III/IV), Fe(III), Co(III), and Pb(IV) oxides/hydroxides are thermodynamically stable in oxygenated systems at neutral pH. However, under anoxic conditions, reductive dissolution of oxides/hydroxides by reducing agents occurs as shown below for MnOOH and MnO$_2$ (Stone, 1991):

$$Mn(III)OOH(s) + 3H^+ + e^- = Mn^{2+} + 2H_2O, \quad E^0 = +1.50\,V,$$

$$(13.25)$$

$$Mn(IV)O_2(s) + 4H^+ + 2e^- = Mn^{2+} + 2H_2O, \quad E^0 = +1.23\,V.$$

$$(13.26)$$
Changes in the oxidation state of the metals associated with the oxides above can greatly affect their solubility and mobility in soil and aqueous environments. The reductants can be either inorganic or organic.

There are a number of natural and xenobiotic organic functional groups that are good reducers of oxides and hydroxides. These include carboxyl, carbonyl, phenolic, and alcoholic functional groups of SOM. Microorganisms in soils and sediments are also examples of organic reductants. Stone (1987a) showed that oxalate and pyruvate, two microbial metabolites, could reduce and dissolve Mn(III/IV) oxide particles. Inorganic reductants include As(III), Cr(III), and Pu(III).

13.5.3.1 Mechanisms for Reductive Dissolution of Metal Oxides/Hydroxides

The reductive dissolution of metal oxides/hydroxides appears to occur in the following sequential steps (Stone, 1986, 1991): (1) diffusion of the reductant molecules to the oxide surface, (2) a surface CR, and (3) release of reaction products and diffusion away from the oxide surface. Steps (1) and (3) are transport steps. The rate-controlling step in reductive dissolution of oxides appears to be surface CR control. Reductive dissolution can be described by both inner- and outer-sphere complex mechanisms that involve (1) precursor complex formation, (2) electron transfer, and (3) breakdown of the successor complex (Figure 13.28). Inner-sphere and outer-sphere precursor complex formations are adsorption reactions that increase the density of reductant molecules at the oxide surface, which promotes electron transfer (Stone, 1991). In the inner-sphere mechanism, the reductant enters the inner coordination sphere by ligand exchange and bonds directly to the metal center prior to electron transfer. With the outer-sphere complex, the inner coordination sphere is left intact and electron transfer is enhanced by an outer-sphere precursor complex (Stone, 1986). Kinetic studies have shown that high rates of reductive dissolution are favored by high rates of precursor complex formation (i.e., large k_1 and low k_{-1} values), high electron transfer rates (i.e., large k_2), and high rates of product release (i.e., high k_3; Figure 13.28).

Specifically, adsorbed cations and anions may reduce reductive dissolution rates by blocking oxide surface sites or by causing release of Mn(II) into solution. Stone and Morgan (1984a) showed that PO$_4^{3-}$ inhibited the reductive dissolution of Mn(III/IV) oxides by hydroquinone. Addition of 10^{-2} M PO$_4^{3-}$ at pH 7.68 caused the dissolution rate to be only 25% of the rate when PO$_4^{3-}$ was not present. Phosphate had a greater effect than Ca^{2+}.

13.5.3.2 Oxidation of Pollutants

As mentioned earlier, Mn oxides can oxidize a number of environmentally important ions that can be toxic to humans and animals. Chromium and plutonium are similar in their chemical

behavior in aqueous settings (Rai and Serne, 1977; Bartlett and James, 1979). They can exist in multiple oxidation states and as both cationic and anionic species. Chromium(III) is quite stable and innocuous and occurs as Cr^{3+} and its hydrolysis products or as $CrO_2{}^-$. Chromium(III) can be oxidized to Cr(VI) by Mn(III/IV) oxides (Bartlett and James, 1979; Fendorf and Zasoski, 1992). Chromium(VI) is mobile in the soil environment and is a suspected carcinogen. It occurs as the dichromate ($Cr_2O_7{}^{2-}$) or chromate ($HCrO_4{}^-$ and $CrO_2{}^-$) anions (Huang, 1991).

Figure 13.29 shows the oxidation kinetics of Cr(III) to Cr(VI) in a soil. Most of the oxidation occurred during the
FIGURE 13.29 Effect of temperature on the kinetics of Cr(III) oxidation in moist Hagerstown silt loam soil. (Reprinted with permission from Amacher, M.C., and D.E. Baker. 1982. Redox reactions involving chromium, plutonium, and manganese in soils. DOE/DP/04515 Pennsylvania State University, University Park, PA.)

first hour. At higher temperatures, there was a rapid oxidation rate, followed by a slower rate. Fendorf and Zasoski (1992) found that Cr(III) oxidation on δ-MnO_2 was more rapid at pH 5 than pH 3 with overall production of Cr(VI) being greater at pH 3 at a Cr(III) concentration of $770\,\mu M$. The rate and extent of Cr(III) oxidation are affected by a number of factors including formation of surface precipitates at higher pHs and Cr(III) concentrations that effectively inhibit oxidation (Fendorf et al., 1992).

Plutonium can exist in the III to VI oxidation states as Pu^{3+}, Pu^{4+}, $PuO_2{}^+$, and $PuO_2{}^{2+}$ in strongly acid solutions (Huang, 1991). Plutonium(VI), which can result from oxidation of Pu(III/IV) by Mn(III/IV) oxides (Amacher and Baker, 1982), is very toxic and mobile in soils and waters.

Arsenic (As) can exist in several oxidation states and forms in soils and waters. In waters, As can exist in the +5, +3, 0, and -3 oxidation states. Arsenite, As(III), and arsine (AsH_3, where the oxidation state of As is -3) are much more toxic to humans than arsenate, As(V). Manganese(III/IV) oxides can oxidize As(III) to As(V) as shown later where As(III) as $HAsO_2$ is added to MnO_2 to produce As(V) as H_3AsO_4 (Oscarson et al., 1983):

$$HAsO_2 + MnO_2 = (MnO_2)HAsO_2, \tag{13.27}$$

$$(MnO_2)HAsO_2 + H_2O = H_3AsO_4 + MnO, \tag{13.28}$$

$$H_3AsO_4 = H_3AsO_4{}^- + H^+, \tag{13.29}$$

$$H_2AsO_4{}^- = HAsO_4{}^{2-} + H^+, \tag{13.30}$$

$$(MnO_2)HAsO_2 = 2H^+ = H_3AsO_4 + Mn^{2+}. \tag{13.31}$$
Equation 13.28 involves the formation of an adsorbed layer. Oxygen transfer occurs and $HAsO_2$ is oxidized to H_3AsO_4 (Equation 13.28). At pH ≤ 7, the predominant As(III) species is arsenious acid ($HAsO_2$), but the oxidation product, H_3AsO_4, will
FIGURE 13.30 Experimental behavior of aqueous As(III), As(V), and Mn(II) following 99.6 μM As(III) addition to a 0.21 g L^{-1} of γ-MnO$_2$ particle suspension at pH 4, 25°C, and 0.1 M NaClO$_4$. (Reprinted from Scott, M.J., and J.J. Morgan. 1995. Reactions at oxide surfaces. 1. Oxidation of As(III) by synthetic birnessite. Environ. Sci. Technol. 29:1898–1905. With permission from American Chemical Society.)

dissociate and form the same quantities of HAsO$_4^-$ and HAsO$_4^{2-}$ with little H$_3$AsO$_4$ present at equilibrium (Equations 13.29 and 13.30). Each mole of As(III) oxidized releases about 1.5 mol H$^+$. The H$^+$ produced after H$_3$AsO$_4$ dissociation reacts with the adsorbed HAsO$_2$ on MnO$_2$, forming H$_3$AsO$_4$, and leads to the reduction and dissolution of Mn(IV) (Equation 13.31). Thus, every mole of As(III) that is oxidized to As(V) results in 1 mol of Mn(IV) in the solid phase being reduced to Mn(II) and partially dissolved in solution (Oscarson et al., 1981).

Oscarson et al. (1980) studied the oxidation of As(III) to As(V) in sediments from five lakes in Saskatchewan, Canada. Oxidation of As(III) to As(V) occurred within 48 h. In general, >90% of the added As was sorbed on the sediments within 72 h. Scott and Morgan (1995) studied the oxidation of As(III) by synthetic birnessite. The depletion of As(III) was rapid with 50% of the initial As(III) removed from solution in 10 min, and after 90 min, the As(III) concentration was below the detection limit. Arsenic(V) was released into solution as fast as As(III) was depleted and the total concentration of aqueous As was about constant over the duration of the experiment (Figure 13.30). Scott and Morgan (1995) concluded that the process of electron transfer and release of As(V) were fast compared to the sorption of As(III), the rate-limiting step.

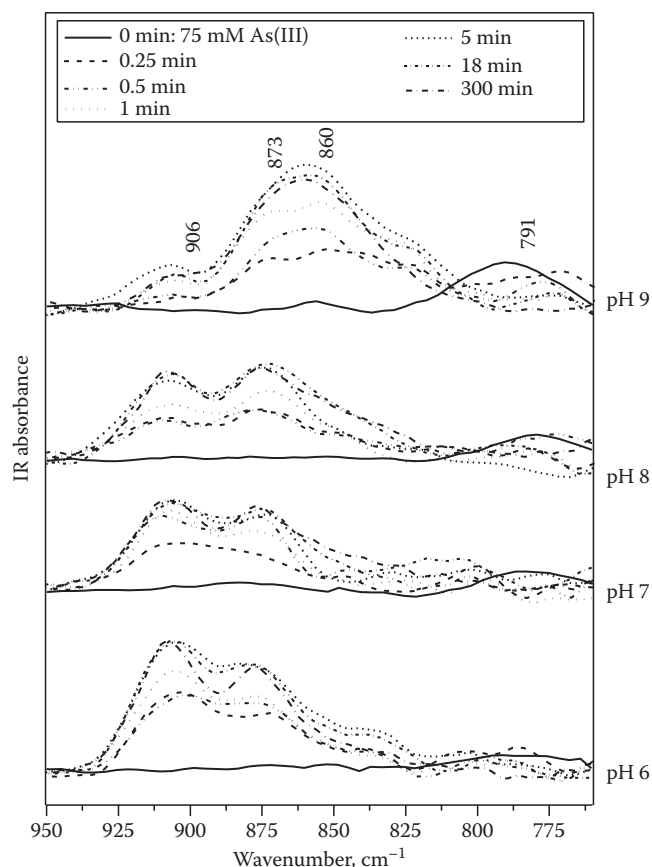
Recently, Parikh et al. (2008), Ginder-Vogel et al. (2009), and Landrot et al. (2010) have used real-time molecular scale ATR–FTIR and QXAS techniques to elucidate the rapid redox kinetics and mechanisms of As(III) oxidation (Parikh et al., 2008; Ginder-Vogel et al., 2009) and Cr(III) oxidation (Landrot et al., 2010) on Mn oxides. Figure 13.31 shows that the oxidation of As(III) on hydrous Mn oxide at pHs of 6–9 is extremely rapid with 50% of the reaction occurring within 1 min. Spectra for times >1 min are very similar with only small differences


FIGURE 13.31 ATR–FTIR spectra for HMO reacted with 75 mmol kg^{-1} As(III) at pHs 6, 7, 8, and 9. Within 1 min of reaction, As(V) peaks (860, 873, and 906 cm^{-1}) are observed and only minimal changes in spectra are observed in a subsequent 300 min period. (Reprinted from Parikh, S.J., B.J. Lafferty, and D.L. Sparks. 2008. An ATR–FTIR spectroscopic approach for measuring rapid kinetics at the mineral/water interface. J. Colloid Interface Sci. 320:177–185. With permission from Elsevier.)

in peak intensities. The reaction process is almost complete in 5 min. Figure 13.32 shows QXAS and traditional batch data for As(III) oxidation on hydrous Mn oxide. An initial concentration of 1.5 mM of As(III) was used. After 1 s of reaction, the As(V) concentration, indicating oxidation of As(III), reached 0.37 mM and continued to increase rapidly for 45 s to reach a concentration of 1 mM. The As(V) concentration continued to increase for the remainder of the reaction, reaching the initial 1.5 mM concentration after 300 s of reaction time (Ginder-Vogel et al., 2009). The initial apparent As(III) depletion rate constants ($t < 30$ s) measured with QXAS were nearly twice as large as rate constants measured with traditional analytical techniques such as the batch method (Ginder-Vogel et al., 2009). Being able to measure the initial reaction rates with these techniques allows one to measure chemical rate constants that are independent of concentration, and, thus, important mechanistic information can be gleaned (Landrot et al., 2010).

Manganese oxides and hydroxides (e.g., Mn$_3$O$_4$ and MnOOH) may also catalyze the oxidation of other trace metals such as Co^{2+},
FIGURE 13.32 As(V) and As(III) concentrations determined from traditional batch and QXAS reactions. Error bars represent the SD of three measurements made at each time point. (Reprinted from Ginder-Vogel, M., G. Landrot, J.S. Fischel, and D.L. Sparks. 2009. Quantification of rapid environmental redox processes with quick-scanning X-ray absorption spectroscopy (Q-XAS). Proc. Natl Acad. Sci. U. S. A. 106:16124–16128. With permission National Academy of Sciences, USA.)

Co^{3+}, Cu^{2+}, Ni^{2+}, Ni^{3+}, and Pb^{2+} by disproportionation to Mn^{2+} and MnO_2 (Hem, 1978). The disproportionation results in vacancies in the Mn oxide structure. Since the Mn^{2+} and Mn^{3+} in the oxides have similar physical sizes as Co^{2+}, Co^{3+}, Cu^{2+}, Ni^{2+}, Ni^{3+}, and Pb^{2+}, these metals can occupy the vacancies in the Mn oxide and become part of the structure. With disproportionation or with other redox processes involving the Mn oxides, the solubility of the metals can be affected. For example, if during the disproportionation process Co_3O_4, the oxidized form of the metal forms from Co^{2+}, the reaction can be expressed as (Hem, 1978)

$$2Mn_3O_4(s) + 3Co^{2+} + 4H^+$$
$$\rightarrow MnO_2(s) + Co_3O_4(s) + 5Mn^{2+} + 2H_2O, \qquad (13.32)$$
and the equilibrium constant (K^o) is (Hem, 1978)

$$\frac{(Mn^{2+})^5}{(Co^{2+})^3(H^+)^4} = 10^{18.73}. \qquad (13.33)$$

Thus, the oxidation of Co(II) to Co(III) reduces its solubility and mobility in the environment. Using XPS analyses (Murray and Dillard, 1979), this reaction has been shown to occur. More recent evidence for heterogeneous redox reactions of trace metals is discussed in Chapter 19. Scott and Morgan (1996) studied the

TABLE 13.5 Inorganic Redox Reactions with Manganese Dioxides

System	Time to Oxidize 50%	Driving Force at pH 4 Δe^o (V)[a]	Source

pH 4, 25°C, 28 m² L⁻¹	16 days	+0.092	
pH 4, 25°C, 14 m² L⁻¹	30 days		
β-MnO_2: Cr(III) $\rightarrow$ Cr(VI) pH 4, 25°C, 71 m² L⁻¹	95 days	+0.011	Eary and Rai (1987)

Source: Reprinted from Scott, M.J., and J.J. Morgan. 1995. Reactions at oxide surfaces. 1. Oxidation of As(III) by synthetic birnessite. Environ. Sci. Technol. 29:1898–1905. With permission American Chemical Society.

[a] The activity ratio for each oxidant/reductant pair is taken as unity.

oxidation of Se(IV) by synthetic birnessite. Se(IV) was oxidized to Se(VI) with Se(VI) first appearing in the aqueous suspension after 12 h and was produced at a constant rate over the duration of the experiment (28 days). Scott and Morgan (1996) suggested the following oxidation mechanisms: (1) birnessite directly oxidized Se(IV) through a surface complex mechanism; (2) the rate-limiting step in the production of Se(VI) was the electron transfer step involving a transfer of two electrons from the anion to the metal ion, breaking of two Mn–O bonds, and addition of an O from water to Se(VI); and (3) the reaction products Se(VI) and Mn(II) were released from the surface by different steps.

Scott and Morgan (1996) compared their results with those of Eary and Rai (1987) who studied Cr(III) oxidation by pyrolusite (β-MnO_2) between pH 3.0 and 4.7 and Scott and Morgan (1995) who studied As(III) oxidation by birnessite (δ-MnO_2) at pH values between 4.0 and 8.2 (Table 13.5). The Cr(III) redox transformation on pyrolusite was slowest which Scott and Morgan (1996) attributed to unfavorable adsorption on both a positively charged surface and aqueous species and the small thermodynamic driving force. Also, the transfer of three electrons from Cr(III) to Mn(IV) requires the involvement of more than one Mn(IV) atom per Cr(III) atom.

Manganese oxides also appear to play an important role in ligand-facilitated metal transport. Using soil columns that consisted of fractured saprolite coated with amorphous Fe and Mn oxides, Jardine et al. (1993) studied the transport of Co(II) $EDTA^{2-}$, a mixture of Co(II) $EDTA^{2-}$ and Co(III) $EDTA^-$ and Sr $EDTA^{2-}$. The Mn oxides oxidized Co(II) $EDTA^{2-}$ into Co(III) $EDTA^-$, a very stable complex (log K value of 41.4; Xue and Traina, 1996). The formation of this complex resulted in enhanced transport of Co.

Xue and Traina (1996) found that an aerobic goethite suspension catalyzed oxidation of Co(II) $EDTA^{2-}$ to Co(III) $EDTA^-$ by dissolved O_2. The kinetics were described using a pseudo-first-order rate constant, k_1 of 0.0078 ± 0.0002 h⁻¹ at pH 5 and a goethite concentration of 3.09 g L⁻¹.

A number of investigators have studied the reductive dissolution of Mn oxides by organic pollutants such as hydroquinone (Stone and Morgan, 1984a), substituted phenols (Stone, 1987b), and other organic compounds (Stone and Morgan, 1984b). With substituted phenols, the rate of dissolution was proportional to substituted phenol concentration and the rate increased as pH decreased (Stone, 1987b). Phenols containing alkyl, alkoxy, or other electron-donating substituents were more slowly degraded; *p*-nitrophenol reacted slowly with Mn(III/IV) oxides. The increased rate of reductive dissolution at lower pH may be due to more protonation reactions that enhance the creation of precursor complexes or increases in the protonation level of the surface precursor complexes that increase electron transfer rates (Stone, 1987b). Further discussions on this topic can be found in Chapter 19.

13.6 Conclusions

Research on the kinetics and mechanisms of soil CRs will be a common theme in soil and environmental sciences for decades to come. This research emphasis is in large part due to the need to more accurately understand and predict the long-term fate and transport of contaminants in the subsurface environment. Without such data, economically sound decisions about soil remediation cannot be made and risk assessment models are incomplete and most probably inaccurate.

While some very fine and informative research on rates and mechanisms of soil CRs/processes has been conducted in the past few decades, there are many gaps that need to be filled. The following research is needed: (1) more accurate kinetic models that describe reactions on multireactive, heterogeneous particle surfaces; (2) long-term sorption and particularly, desorption rate studies; (3) a better understanding of residence time effects on plant nutrient, radionuclide, metal, and organic retention/release mechanisms on soils and other natural materials; (4) an increased knowledge of nucleation/precipitation and dissolution reaction rate phenomena at the mineral/water interface and their effect on nutrient/contaminant mobility and bioavailability in the soil environment; (5) more studies on the kinetics and mechanisms of redox processes in soils, particularly the role that soil components such as Mn oxides have on oxidation/reduction of inorganic and organic pollutants; and (6) increased use of real-time molecular scale in situ spectroscopic and microscopic techniques to confirm reaction mechanisms.

14.1 Concepts, Principles, and Theories

14.1.1 Nature of the Electron and Proton in Soil Solutions

Electrons are subatomic particles with wave-like properties that have defied exact characterization since their discovery in 1897, despite their central role in chemical reactions (Castellan, 1983). Electrons are considered fundamental subatomic particles, but recent findings suggest that they may possess a substructure of leptoquarks, that electron orbitals do not exist, and that the role of electrons in predicting periodicity of the elements is only approximate (Scerri, 1997). In addition, new frontiers are expanding to explain electron-transfer processes at interfaces (Tributsch and Pohlmann, 1998). Studying and understanding electron-transfer processes in soils, therefore, is challenging and must be based on sources of information from relatively simple aqueous systems and natural waters, as well as on a large base of empirical studies using soils. Electron-transfer processes in microbial cells are central to nutrient and pollutant chemical reactions, especially oxidation state changes governed by intra- and extracellular enzymes (Paul, 2007). Recent developments in environmental microbiology have found that bacteria form biofilms almost ubiquitously in aqueous and colloidal environments, such as natural waters, soils, and the human body (Stoodley et al., 2004). Therefore, understanding the role of microbes in controlling redox processes in soils requires an appreciation of such "matrix enclosed accretions that adhere to biological and nonbiological surfaces" (Stoodley et al., 2004).

To understand and characterize the nature of "electron activity" and oxidation–reduction reactions in biotic and abiotic, heterogeneous, multiphase soils and soil solutions, an appreciation of the characteristics of electrons and closely allied protons is needed (James, 1989; Stumm and Morgan, 1996; Bartlett, 1998; Bartlett and Ross, 2005). An examination of the complementary nature of electrons and protons affirms the importance of hydrogen ion and electron activities as master variables in soils (Sillén, 1967).

The H atom comprises one proton and one electron, and it may be visualized as a spherical puff of cotton candy with a radius of approximately 10 cm and a proton nucleus with a radius of 5 μm; essentially an invisible fleck of unspun sugar in the center. The remaining volume of the atom is occupied by the electron and the density of the spun sugar represents the probability of finding the electron in any one location. It becomes increasingly less dense (less probable) with distance away from the positively charged proton (Castellan, 1983). The radius of the H atom (0.3 Å), therefore, is approximately 20,000 times greater than that of the proton ($\sim 1.5 \times 10^{-5}$ Å). The proton also may be visualized as the size of a 0.1 μm colloidal clay particle, compared to a 2000 μm sand grain in a soil. In contrast to the large proportion of the volume of the H atom occupied by the negatively charged, wave-like electron, the electron has only negligible mass equal to approximately 550 μg mol^{-1}, 1/1836 of the mass of the H atom (10^6 μg mol^{-1}).

The tiny, heavy proton persists in hydrated form in aqueous media as H_3O^+, the hydroxonium or hydronium ion. The H atom

can only form the H^+ ion when its compounds are dissolved in media that solvate protons, so the H^+ cannot exist in solid phases (Cotton and Wilkinson, 1980). The solvation enthalpy of $-1091\,kJ$ mol^{-1} provides the energy for bond rupture. Protons migrate rapidly between water molecules, and an individual H_3O^+ ion has a lifetime of approximately 10^{-13} s. Its concentration and activity can, therefore, be measured and understood in terms of the hydration of a cation in solution. The single ion activity coefficient can be calculated based on ionic strength, temperature, effective diameter, and solvent characteristics; and H^+ activity can be calculated or measured (Westcott, 1978; Bates, 1981).

The extremely large "charge-to-size ratio" of the electron prevents it from persisting in free form in aqueous systems, as does the solvated H^+. The ephemeral "hydrated electron" is a powerful reducing agent with a potential of $-2.7\,V$ relative to the H^+/H_2 reference potential of $0.0\,V$ and has a half-life of $<1\,ms$. It reacts rapidly with second-order rate constants of 10^8–10^{10} M^{-1} s^{-1}, near the diffusion-controlled limit (Sullivan et al., 1976). Hydrated electrons may be transferred to aqueous solution from photoexcited hydrocarbons as $\bullet e_{aq}^-$. Such "free" or "aqueous" electrons react with H_2O and H_3O^+ at femtosecond rates (10^{-15} s) to form the "conjugate acid" of the electron, $H^\bullet$, and the reaction with H_3O^+ is approximately 10^7 times faster than with water (Leffler, 1993). The role of such aqueous electrons in soils remains unstudied, and photochemical studies of soils may reveal their presence and importance.

In soil chemical calculations and theory, one considers the electron as a "species," designated "e^-," with negligible mass and thermodynamically as a ligand, reactant, and product (Sposito, 1981). The electron is not ionic, but it is "negatively charged" as the carrier of negative electricity (Thompson, 1923). Its "activity" is conceptually analogous to that of H^+, but its concentration in "mol L^{-1}" is undefined. All these caveats about the electron require that one understand that electron activity in soils and natural waters should be regarded as related strictly to energy functions. Such functions can be described simply as "the ability to do work," "electrochemical potential," and more colloquially, "electron pressure."

Generically, for a reduction half-reaction: ox + ne$^-$ = red, the electron activity, (e^-), equals $[(red)/K(ox)]^{1/n}$, in which "ox" is the oxidized species, "red" is the reduced species, n is the number of moles of electrons, and K is the equilibrium constant. Therefore, electron activity is a function of the ratio of reduced-to-oxidized species activities and of the equilibrium constant [or Gibbs free energy for the reaction, since $\Delta G_r^o = -RT\ln K$, where R is the gas law constant ($8.313\,J\,K^{-1}\,mol^{-1}$) and T is the absolute temperature measured in Kelvin ($298\,K$ under standard conditions)]. A "favorable reaction" with a large positive value for K (or large negative ΔG_r^o) will therefore be associated with low electron activity. For example, a value of the equilibrium constant, $K = 6 \times 10^8$, corresponds to $\Delta G_r^o = -50\,kJ\,mol^{-1}$ and $K = 57$ corresponds to $-10\,kJ\,mol^{-1}$ (Compton and Sanders, 1996). That is, such reactions will proceed spontaneously at relatively low electron activities or pressures, corresponding to positive electrode voltages. In these examples, since $\Delta G_r^o = -nFE^o$, the voltages

(E^o) associated with the electron transfers are $+5.2$ and $+1.04\,V$, respectively, where n is the number of moles of electrons and F is the Faraday constant [96,487 C (coulombs) mol^{-1} or $J\,V^{-1}\,mol^{-1}$].

The concept of H^+ activity and pH also can be described in terms of thermodynamic work (Δw) defined as the product of an intensive property and extensive variation, such as P (ΔV), where P is pressure and ΔV is change in volume (Stumm and Morgan, 1996). Similarly, electron activity may be defined as E (Δe), where E is potential and Δe is change in charge of the system. Proton and electron activities also may be defined as chemical work, μ (Δn), where μ is chemical potential and Δn is change in moles (Sposito, 1981).

Viewing the sibling concepts of "proton activity" and "electron activity" in soils, they must not be considered twins. Recognition must be given to similarities and differences in the formulation of conceptual and operational definitions for these key variables, and such comparisons are based on the differences in the nature of the proton and electron, as described above. In both cases, however, their thermodynamic activities in a given system are relative to their activities under standard-state conditions. In the case of the e^-, the standard state is at $(H^+) = 1\,M$, a partial pressure of $H_2 = 1\,atm$, and a temperature of $298\,K$, characteristics of the standard hydrogen electrode (SHE) with $0\,V$ under these conditions (Lindsay, 1979; Compton and Sanders, 1996; Stumm and Morgan, 1996). For H^+ activity, the reference state is $1\,M$ or pH 0 (Bates, 1981).

The familiar concept of buffer capacity for pH is defined as the change in acid or base added (capacity factor) to effect a one unit change in pH (intensive variable; Stumm and Morgan, 1996). Similarly, the "capacity factor" in redox is referred to as poise and is defined as the change in added equivalents of reductant or oxidant to bring about a one unit change in pe (–log of electron activity) or an Eh (voltage relative to the SHE) change of $59\,mV$, as discussed in Section 14.1.2. Poise in soils and natural waters has been less intensively studied than pH buffering, but it is a central concept governed by reductant and oxidant activities and microbial processes.

The choice of oxidant or reductant to add in a redox titration will affect the calculated poise (resistance to change in pe as measured by the Pt electrode), and poise will be operationally defined by the couple interacting with the Pt wire. For instance, if the soil is titrated with Cr(VI), the Cr(VI)–Cr(III) couple will be potential determining, so the poise will reflect that pe range. If Fe(II) were added, the Fe(III)–Fe(II) couple would set a lower pe range than would Cr(VI)–Cr(III). Heron et al. (1994) titrated aquifer sediments with the reducing agent, Ti^{3+} EDTA, to determine the poise associated with oxidants, such as Fe(III) and Mn(III,IV) (hydr)oxides. Barcelona and Holm (1991) titrated with Cr^{2+} to quantify poise due to oxidants, and with $Cr_2O_7^{2-}$ to determine poise governed by reductants in the soil, respectively. Bauer et al. (2007) measured electron-transfer capacities and reaction kinetics of peat-dissolved organic matter, an organic matter analog for soil C. They used Zn and H_2S oxidation and complexed Fe(III) reduction to show that dissolved organic matter is a redox poising system between -0.9 and $1.0\,V$.

Redox intensity measurements (Eh or pe) and estimates of poise as the redox capacity of soils and sediments are also distinguished from those only associated with H^+ in that microbial

catalysis controls the rates of many of the oxidation and reduction reactions governing soil redox status (Russell, 1973; Banerjee, 2008). Also, the adaptation and growth of higher plants and algae in soils affects redox intensity and capacity. Examples of such microbial processes governing redox in soils include Fe(III) and SO_4^{2-} reduction in sediments (Coleman et al., 1993), denitrification in soil microenvironments (Højberg et al., 1994), N_2 fixation in flooded soils (e.g., due to pH and pe changes by the *Anabaena–Azolla* symbiosis in rice or that of the *Frankia* sp. actinomycete infection of alder (*Alnus* spp.; Buresh et al., 1980; Madigan and Martinko, 2006), methane oxidation in flooded rice soils (Wang et al., 1997), the reactions of H_2 in anoxic groundwater (Lovley et al., 1994), methanogenesis (Welsch and Yavitt, 2007; Goldhammer and Blodau, 2008; Saggar et al., 2008), and the formation of oxidized root channels (rhizospheres) in soils (Mendelssohn et al., 1995).

The poise and pe of soils also differ from natural waters in that the solids-to-solution ratio is high; and subsequently, redox reactions across colloid–solution interfaces are centrally important. Biofilm–water interfaces may be especially important in the case of microbially governed redox processes. Relatively few studies have been reported on redox reactions across soil colloid–water interfaces, but this area is critically important for predicting oxidation state and potential mobility of nutrients and pollutants in soil environments. Examples include reductive dissolution of Fe(III) and Mn(III,IV) (hydr)oxides and redox reactions on such surfaces or with constituent ions (Bartlett and James, 1979; Stone and Morgan, 1987; Suter et al., 1991; Stumm and Sulzberger, 1992; Postma and Jakobsen, 1996; White and Peterson, 1996).

14.1.2 Thermodynamic Relationships for Electron Activity in Soils

Since electrons are transferred from reductants (e^- donors or reducing agents) to oxidants (e^- acceptors or oxidizing agents) and do not persist free in soil solution, reduction reactions must be coupled to oxidation reactions to describe complete oxidation–reduction processes (redox reactions). By convention, reduction half-reactions can be written and thermodynamic relationships derived from them, despite the fact that they do not occur in isolation. The log K values (where K is the equilibrium constant for the half-reaction) for the coupled reactions may be compared to predict the likelihood of a reaction occurring spontaneously as written.

For example, development of reduction half-reactions to predict whether gaseous H_2S could reduce colloidal FeOOH across a sulfidic–aerobic interface in a wetland soil may be completed in the following manner:

1. Write the oxidized and reduced species on the left and right sides of the equation, respectively, with the appropriate number of electrons per mole of oxidant written on the left side. Balance moles of elements other than O and H:

$$FeOOH + e^- = Fe^{2+}, \tag{14.1}$$

$$SO_4^{2-} + 8e^- = H_2S. \tag{14.2}$$
The number of electrons needed for reduction is calculated from the oxidation numbers or states of the elements in the oxidized and reduced species (Vincent, 1985). In this example, the oxidation numbers are III+ and VI+ for Fe and S in FeOOH and SO_4^{2-}, respectively.

2. Add H_2O to the equation (usually to the right side) to balance the moles of O:

$$FeOOH + e^- = Fe^{2+} + 2H_2O, \tag{14.3}$$

$$SO_4^{2-} + 8e^- = H_2S + 4H_2O. \tag{14.4}$$
3. Then add H^+ to balance moles of H, usually on the left side of the equation:

$$FeOOH + e^- + 3H^+ = Fe^{2+} + 2H_2O, \tag{14.5}$$

$$SO_4^{2-} + 8e^- + 10H^+ = H_2S + 4H_2O. \tag{14.6}$$
4. Check charge and mass balances for the equations.

These equations can now be used to develop expressions for electron activity based on equilibrium expressions and free energy of formation (ΔG_f^o) data.

The principles for doing this can be understood by starting with a generic reduction half-reaction:

$$Aox + Be^- + CH^+ = Dred + EH_2O \tag{14.7}$$
where A, B, C, D, and E are the stoichiometric coefficients. The expression for the equilibrium constant (K) is as follows:

$$K = \frac{\left[(red)^D (H_2O)^E\right]}{\left[(ox)^A (e^-)^B (H^+)^C\right]} \tag{14.8}$$

where
() denotes activity
(H_2O) has a value of 1, by convention

Taking the log of both sides of the equation,

$$\log K = \log\left[\frac{(red)^D}{(ox)^A}\right] + \log\left[\frac{1}{(e^-)^B}\right] + \log\frac{1}{(H^+)^C} \tag{14.9}$$

and

$$\log K = D\log(red) - A\log(ox) + Bpe + CpH \tag{14.10}$$

where
pe and pH are defined as −log electron activity
H^+ activity, respectively.

The "p" notation means power and denotes the exponent for the H^+ activity (pH 4 or 10^{-4} mol H^+ kg^{-1} water). Therefore, $(H^+) = 10^{-pH}$. In contrast, the exponent for e^- activity is not 10^{-pe}, since the electron

activity is not defined in terms of "mol e⁻ L⁻¹." Both pe and pH are analogous, though, if viewed as related to the ability of e⁻ and H⁺ to do thermodynamic work (Section 14.1.1).

Further rearrangement of Equation 14.10 yields a pe–pH relationship of the following form:

$$\left[\left(\frac{1}{B}\right)\log K - \left(\frac{D}{B}\right)\log(\text{red}) + \left(\frac{A}{B}\right)\log(\text{ox})\right] - \left(\frac{C}{B}\right)\text{pH} = \text{pe},$$

(14.11)

which gives a straight line with slope C/B and the intercept in square brackets that is a function of log K for the half-reaction and the activities of the oxidized and reduced species.

For a one-electron transfer (B = 1) coupled with one-proton consumption (C = 1), and when D = A and (red) = (ox),

$$\text{pe} + \text{pH} = \log K. \qquad (14.12)$$

And when pH = 0 (standard state),

$$\text{pe} = \log K. \qquad (14.13)$$

Knowledge of pe and pH is pertinent to describing the equilibrium condition of a soil as defined by the master variables, pe, pH, and their sum (Lindsay, 1979). The concepts of electron activity and hydrogen ion activity are closely coupled and cannot be separated in assessing the oxidation–reduction status of a soil system. The pe + pH parameter has been described metaphorically by Bartlett (1998) as a seesaw with a hungry baby bird on one side (the electron-deficient player) and earthworms on the other (the electron-rich source). The parent bird carries the earthworms to the baby, representing electron transfer and causing a shift in the position of the seesaw, quantified by the pe–pH balance. As worms are transferred, the pe increases and the pH decreases, countering and interacting controls on the redox equilibrium. As the worms are consumed by the baby, the seesaw shifts back again, representing a dynamic, metastable system governed by the flow of energy and the cycling of nutrients, characteristics of ecosystems. The position of the seesaw governed by pe and pH reflects the equilibrium condition of a soil, and the values of pe and pH are intensity measures of redox status. The change in measured pe and pH per mole of electrons plus H⁺ (H atoms in principle) transferred reflects the buffer capacity or poise of the system, $\Delta(\text{pe} + \text{pH})/\Delta$ (mol H atoms transferred).

To relate the concept of log K to the Gibbs free energy change (ΔG_r^o) for a given half-reaction in the soil, the following expressions are pertinent:

$$\Delta G_r^o = -RT \ln K \qquad (14.14)$$

where

ΔG_r^o is Gibbs free energy of reaction under standard conditions (298 K and 1 atm)

R is the universal gas law constant (0.00831 kJ K⁻¹ mol⁻¹)

T is absolute temperature (298 K)

Converting to log₁₀ (ln K = 2.303 log K) yields the following:

$$\frac{\Delta G_r^o}{-5.70} = \log K. \qquad (14.15)$$

log K may therefore be estimated simply from knowledge of free energies of formation of H_2O, the red, and the ox; since those of H⁺ and e⁻ are zero, by convention. To relate log K directly to pe as defined by Equation 14.11 for one-electron transfers, log K values must be divided by B, the mol of e⁻ consumed in the reaction. Therefore, pe at a given pH and other defined conditions is equivalent to log K, and the parameter pe + pH couples the master variables in defining the equilibrium redox state of a soil–water system.

Log K values also are related to thermodynamic electrochemical potentials (Eh) according to the following expressions (Compton and Sanders, 1996):

$$\Delta G_r^o = -nFEh \qquad (14.16)$$

where

n is the number of e⁻ transferred mol⁻¹

F is the Faraday constant (96.5 kJ V⁻¹ equivalent⁻¹ or 96,487 C mol⁻¹ where C is coulombs, derived from 1.60×10^{-19} C/e⁻ × 6.02×10^{23} e⁻/mol)

Since both Equations 14.16 and 14.14 are expressions for ΔG_r^o,

$$-nFEh = -RT \ln K \qquad (14.17)$$

and, when T = 298 K,

$$Eh = \frac{RT\, 2.303 \log K}{nF} = 0.0592 \log K. \qquad (14.18)$$

If n = 1, (red) = (ox), and pe = log K at a given pH (Equation 14.12), then

$$Eh\ (V)\ =\ 0.0592\,\text{pe} \qquad (14.19)$$

or

$$\frac{Eh}{0.0592} = \text{pe}. \qquad (14.20)$$

Therefore, calculating or interpreting Eh values rigorously and linking soil measurements to thermodynamics require knowledge of the pH of the soil–water system.

Applying these principles to the H_2S–FeOOH problem above (Equations 14.5 and 14.6), the following pe–pH expressions can be derived:

For FeOOH–Fe²⁺:

$$\text{pe} = \log K_{Fe} - \log(Fe^{2+}) - 3\text{pH} \qquad (14.21)$$

where activity of FeOOH is assumed to be 1, an assumption that may or may not be valid for redox processes (Stumm, 1993; White and Peterson, 1996).

For SO_4^{2-}–H_2S:

$$pe = \frac{1}{8}\log K_S - \frac{1}{8}\log\left[\frac{P_{H2S}}{SO_4^{2-}}\right] - \frac{5}{4}pH \qquad (14.22)$$

where

K_{Fe} and K_S are the equilibrium constants for the FeOOH and SO_4^{2-} reduction half-reactions

P_{H_2S} is the partial pressure of H_2S

Calculating log K values and substituting into Equations 14.21 and 14.22 yield the following:

$$pe = 13.0 - \log(Fe^{2+}) - 3pH \qquad (14.23)$$

and

$$pe = 5.21 - \left(\frac{1}{8}\right)\log\left[\frac{P_{H_2S}}{SO_4^{2-}}\right] - \left(\frac{5}{4}\right)pH. \qquad (14.24)$$

At defined activities for the ions and partial pressure for H_2S, pe may be calculated, and if pe for Fe(III) reduction > pe for SO_4^{2-} reduction, then FeOOH will be reduced to Fe^{2+} and H_2S oxidized to SO_4^{2-} at equilibrium and at the hypothetical soil interface. The same result will be obtained if after subtracting the log K value for S from that for Fe, a positive answer is obtained.

The Equations 14.23 and 14.24 can be plotted on an *x–y*-graph called a pe–pH diagram (Figure 14.1). In this graph, each reduction half-reaction is plotted for (red)/(ox) = 1 and 10^{-4}. Note that
FIGURE 14.1 pe–pH diagram for FeOOH–Fe^{2+} and SO_4^{2-}–H_2S equilibria at two activity ratios.

the positions of the lines are shifted to higher pe values for the lower activities of the reduced species; the effect being greater for the FeOOH–Fe^{2+} couple than for SO_4^{2-}–H_2S, due to the greater oxidation state change per mole for S than for Fe. This effect of changing the activity ratio on pe values is an easy way to perform a sensitivity analysis for these thermodynamic models and to plot a family of curves representative of a range of activities relevant to any soil system or conditions. Similar calculations can be performed for variations in the values of ΔG_f^o, since the conditions (e.g., temperature, pressure, and ionic strength) under which these values are determined may result in a range of values of up to 10 or more kJ mol^{-1}. The ΔG_f^o values tabulated by Lindsay (1979) were reviewed and selected for their accuracy and their relevance to soils and natural waters.

An important use of pe–pH diagrams is for predicting thermodynamically whether or not the oxidized species in one reduction half-reaction will oxidize the reduced species in a second reduction half-reaction (i.e., when the second half-reaction is reversed to become the oxidation half-reaction and is added to the first reduction half-reaction). When the line for a pe–pH couple is above another over a pH range, the calculated Δpe or ΔEh values will be >0 (and corresponding ΔG_r^o values <0), signifying that the reaction is spontaneous as written. In the above example, FeOOH is expected to oxidize H_2S over the pH range 0–6.6 for the activity ratio = 1 but only up to pH 4.6 for the activity ratio = 10^{-4}. Theoretically, above the crossover pH values, SO_4^{2-} would be expected to oxidize Fe^{2+} to FeOOH, while being reduced to H_2S; the opposite of the reaction at pHs < the crossover value.

Calculations of myriad pe–pH relationships are conveniently performed using a spreadsheet template that incorporates balanced half-reactions, appropriate ΔG_f^o values to calculate log K, chosen activity ratios, and Equation 14.11. Using such a spreadsheet, numerous pe values for common reduction half-reactions pertinent to soil chemical and biochemical processes were calculated and are presented in Table 14.1. Table 14.1 also includes numerous pe values derived from Eh data in various published databases, especially for coenzymes and some intermediates governing microbial respiration. This list provides a quick, semi-quantitative means of assessing what the products of selected, coupled reduction and oxidation half-reactions are likely to be.

The U.S. Environmental Protection Agency developed MINTEQ (for "Mineral Thermal Equilibria"), a DOS-based computer program that calculates the distribution of myriad species based on minimizing the Gibbs free energy of a system of multiple chemical equilibria. Different from earlier such programs, such as GEOCHEM, it incorporates algorithms for redox reactions and allows the estimation of pe, pH, and reductant and oxidant activities in conjunction with dissolution and exchange equilibria. The use of MINTEQ also permits an easy way to conduct a sensitivity analysis for estimated pe, pH, or ion activities when just one value for a given parameter is varied (Allison and Brown, 1995). Visual MINTEQ was written and is updated for Microsoft Windows by J.P. Gustafsson, and version 3.0 (as of August 2010) is now available free online at http:/www.lwr.kth.se/English/OurSoftware/vminteq/

TABLE 14.1 Reduction Half-Reactions for Soils

	Log K^a	pe^b	
	(pe at pH 0)	pH 5	pH 7
Nitrogen species

[a] Calculated for reaction as written according to Equation 14.14. Free energy of formation data were taken from Lindsay (1979) as a primary source, and when not available from that source, from Garrels and Christ (1965) and Loach (1976).

[b] Calculated using tabulated log K values, (red) and (ox) = 10^{-4} mol/L soluble ions and molecules, activities of solid phases = 1, and partial pressures for gases that are pertinent to soils: 10^{-4} atm for trace gases, 0.21 atm for O$_2$, 0.78 for N$_2$, and 0.00032 for CO$_2$. Note: pe × 59.2 = Eh (mV) at the specified pH.

[c] Values not listed by Loach (1976) or Larson (1997).

[d] Values from Larson (1997).

[e] Value for 4 M Cl$^-$ in Ag/AgCl reference electrode.

14.1.3 Kinetic Derivation of Thermodynamic Parameters for Redox

This thermodynamic derivation of log K and its relationship to pe and pH of soils is based on free energy of formation data for oxidants and reductants, and it is not related to reaction mechanisms or rates. An alternate procedure to obtain log K values, in theory, is the kinetic approach suggested by Sparks (1985) for cation exchange and by Harter and Smith (1981) for adsorption processes. This approach has been little used in redox soil chemistry, probably due to difficulties in obtaining rate coefficients for many electron-transfer processes in soils and due to the irreversibility of most redox reactions. The application of such approaches should, however, be appropriate for certain reversible redox reactions in soils, especially in situations where metastability and lack of chemical equilibrium prevail or when accurate free energy of formation data is unavailable for oxidants and reductants.

In principle, this is the method for calculating kinetic parameters: the equilibrium constant (K) for redox equilibria can be estimated from the ratio of forward and reverse rate coefficients for a given reversible reaction in soils:

$$K = \frac{k_f}{k_r} \tag{14.25}$$

where k_f and k_r are the rate constants for forward and reverse reactions, respectively. The standard Gibbs free energy for the reaction then can be calculated by substituting ln K into Equation 14.14. Preparation of Arrhenius plots of the rate coefficients as a function of 1/T permits estimation of activation energies for the forward and reverse reactions, and standard enthalpies for the reactions can be calculated as

$$\Delta H^o = E_f^\star - E_r^\star \tag{14.26}$$

where

ΔH^o is enthalpy for the redox reaction

$E_f^\star$ and $E_r^\star$ are the activation energies for the forward and reverse reactions

With knowledge of ΔG^o and ΔH^o, standard entropy of the reaction can be calculated as

$$\Delta S^o = \frac{\Delta H^o - \Delta G^o}{T}. \tag{14.27}$$

Since the e^- and H^+ are key reactants and products in the thermodynamic sense, a refined knowledge of mechanisms for particular redox reactions is needed because of our current limitations in understanding how similar or different e^- and H^+ reactions are in soils and natural waters. Knowledge of thermodynamic stability for a redox system does not necessarily predict kinetic lability, a concept directly pertinent to reactivity of different types of complexes (Cotton and Wilkinson, 1980). The kinetic lability of redox processes in soils has not been compared systematically with predictions of stability based on thermodynamic data,

but linear free energy relationships (LFERs) are useful plots of observed rate constants versus equilibrium constants or Eh values (Stumm and Morgan, 1996; Bürge and Hug, 1997). Such information could affirm the reliability of using thermodynamic data to predict bioavailability of nutrients and pollutants, and to estimate true reactivity of electron donors and acceptors in nonequilibrium, kinetically governed soil chemical and microbial environments.

Given the constraining limitation of irreversibility of most redox reactions in soils, especially microbial ones, for using experimental data to calculate values for thermodynamic parameters, the use of kinetic knowledge on soil redox processes is less widely used than are pe (and Eh) and pH for assessing equilibrium conditions of soils. Empirical studies in relatively pure, aqueous systems, and complex soil suspensions have, however, provided pertinent information on the kinetics of redox processes and their relation to thermodynamic parameters and reaction pathways (Stumm, 1992, 1993; Stumm and Morgan, 1996; Hug et al., 1997; Typrin, 1998).

14.1.4 Microbiological and Enzymatic Controls for Redox State and Processes in Soils

Bacterial metabolism, the process of producing adenosine triphosphate (ATP) through a series of catabolic reactions and building cell constituents with anabolic reactions, requires energy, electrons, nutrients, and either oxygen or another highly oxidized compound to serve as a terminal electron acceptor (TEA; Sylvia et al., 2005). Bacteria that use O_2 as the electron acceptor are aerobic, those that utilize another oxidized compound in the absence of oxygen are anaerobic, and those capable of both are facultative anaerobes. The use of external TEAs intricately links bacteria to important geochemical processes, such as denitrification, methane production, and metal reduction (Salminen et al., 2006; Banerjee, 2008).

The metabolic classification of bacteria is based on the energy source, electron source (reducing equivalents), and carbon source used in catabolic and anabolic processes. Bacteria can derive energy from natural sunlight or from chemical reactions. Phototrophy is the process of using natural light for energy, as employed by photosynthesizing algae or cyanobacteria, whereas chemotrophy requires a chemical reaction for metabolic growth (Madigan and Martinko, 2006). All nonphotosynthetic cellular organisms utilize this pathway to derive the energy needed for metabolic reactions. Electrons (reducing equivalents) can be derived from either organic or inorganic compounds. Organotrophy is the process of using organic compounds, and lithotrophy is that of using inorganic compounds. Organotrophic bacteria are generally associated with chemotrophy; however, lithotrophic bacteria can be either phototrophs or chemotrophs. Cellular C needed for metabolic processes can be derived from organic compounds, which is referred to as heterotrophy, or from CO_2 (dissolved CO_2, H_2CO_3, HCO_3^-, or CO_3^{2-} in natural waters and soil solution; the predominant

species depending on pH), which is autotrophy. Autotrophy is generally linked with lithotrophy, and heterotrophy is associated with organotrophy (Sylvia et al., 2005).

The oxidation of an organic or inorganic compound and reduction of O_2 or other oxidized species during bacterial metabolism is the coupling of oxidation–reduction half-reactions (redox processes) and is the basis for bioenergetics. Biologically mediated redox reactions in soils are linked to metabolic processes and will follow a thermodynamic sequence based on the energetic possibility of the reaction (Stumm and Morgan, 1996). Aerobic chemoorganoheterotrophs use organic C compounds as a source of energy, electrons, and C; and they use O_2 as the TEA. The half-reactions for the reduction of O_2 and oxidation of an organic compound (generically represented by CH_2O with the oxidation state of C = 0) from Table 14.1 can be coupled to show that the overall $\Delta G_r^o = -130 \, kJ \, mol^{-1}$. An anaerobic chemoorganoheterotroph present in an O_2-depleted environment, such as a wetland soil, can utilize the same C source but would require another TEA. Using $Fe(OH)_3$ instead of O_2 from Table 14.1 would result in an overall $\Delta G_r^o = -102 \, kJ \, mol^{-1}$. This example illustrates how the use of O_2, when available, is thermodynamically more favorable for metabolic growth than other oxidized species.

The reduction of O_2 to H_2O in aerobic respiration involves four, one-electron reduction steps, shown with pe values at pH 7:

$$O_2 + e^- + H^+ = HO_2^\bullet$$

Formation of superoxide radical (pe = −7.8),   (14.28)

$$HO_2^\bullet + e^- + H^+ = H_2O_2$$

Formation of hydrogen peroxide (pe = 17.9),   (14.29)

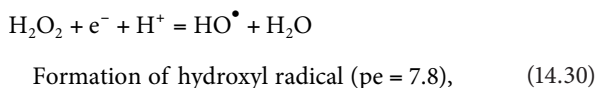
$$H_2O_2 + e^- + H^+ = HO^\bullet + H_2O$$

Formation of hydroxyl radical (pe = 7.8),   (14.30)

$$HO^\bullet + e^- + H^+ = H_2O$$

Formation of water (pe = 36.8),   (14.31)

$$\frac{1}{4}O_2 + e^- + H + = \frac{1}{2}H_2O$$

Overall reaction (pe = 13.6).   (14.32)


An examination of the pe values for the stepwise reduction of O_2 to H_2O demonstrates that even though the overall reaction has a pe = 13.6 (confirming that it is a good oxidizing agent), superoxide, hydrogen peroxide, and hydroxyl radical intermediates are more powerful oxidants than O_2. Superoxide dismutase or reductase, catalase or peroxidase, and glucose-6-dehydrogenase are essential enzymes used by aerobic cells. They dismutate superoxide and hydrogen peroxide and subsequently reduce hydroxyl radicals more rapidly than the reactive oxygen

species can react with cell constituents, thereby allowing aerobic respiration to proceed. Hydroxyl radicals are rarely formed in microbial cells due to the efficiency of H_2O_2 dismutation to H_2O and O_2, following reduction of $HO_2^\bullet$. Deficiencies of some or all of these enzymes render soil microbes incapable of respiration under fully aerobic conditions but better adapted to microaerophilic or anaerobic conditions (Madigan and Martinko, 2006).

In aerobic respiration, the coupling of C oxidation to O_2 reduction occurs within the bacterial cell either by substrate-level phosphorylation or oxidative phosphorylation, which is carried out by an intermediate compound such as the coenzyme nicotinamide adenine dinucleotide (NAD^+) or nicotinamide adenine dinucleotide phosphate ($NADP^+$) Madigan and Martinko, 2006). Although intermediaries are utilized in oxidative phosphorylation, the overall net change in energy is the difference in reduction potential between the primary electron donor and TEA. The electron-carrying coenzyme NADH or NADPH transfers electrons to a series of four complexes of the mitochondrial respiratory chain, which conserves energy by proton pumping, which further drives the synthesis of ATP (Banerjee, 2008). It is at complex IV, the final complex of electron transfer in oxidative phosphorylation, that oxygen is reduced to water by cytochrome c oxidase in a four-electron, one-step reaction (Equations 14.28 through 14.31). In substrate-level phosphorylation, ATP is directly produced in the enzymatic oxidation of an organic substance but with much lower yields than obtained via oxidative phosphorylation (Madigan and Martinko, 2006).

Calculating the Gibbs free energy of a reaction may indicate that the use of an electron donor and acceptor in a reaction is thermodynamically favorable, but it does not indicate at what rate the reaction would occur. The use of a substrate, although energetically favorable, may not occur at a biologically relevant rate without the catalytic action of an enzyme. Enzymes are proteins configured in secondary, tertiary, or quaternary structures that allow for specific binding properties and often contain non-protein prosthetic groups, cofactors, and coenzymes that participate in the catalytic functions of the enzyme (Madigan and Martinko, 2006). In order to obtain substrates located outside of the cell, enzymes (e.g., hydrolases) can be excreted to break down insoluble polymers such as cellulose, starch, and proteins. These degraded macromolecules are then transported into the cell for use in metabolic reactions (Sylvia et al., 2005). Soil microorganisms using extracellular enzymes are important in the initial depolymerization of cellulose. White rot and brown rot fungi are key microorganisms in the breakdown of cellulose, hemicellulose, and lignin in woody plant tissue in contact with soil.

Either through intracellular or extracellular mechanisms, once substrates are in the cell; oxidative phosphorylation requires a TEA, and in oxygen-depleted environments, bacteria must use alternative oxidized species. Nitrate (NO_3^-), Fe(III) (hydr)oxides, Mn(III,IV) (hydr)oxides, SO_4^{2-}, and CO_2 are oxidized species found in soil, which can be reduced in the terminal step of oxidative phosphorylation, and the reduced forms are excreted from the cell (Sylvia et al., 2005). The reduction of

nitrate coupled to the oxidation of pyrite in anoxic groundwater sediments was recently demonstrated to be a biologically driven redox process (Jorgensen et al., 2009).

In addition to soluble constituents, such as NO_3^- or SO_4^{2-}, as TEAs, the use of less soluble minerals, such as Fe(III) (hydr)oxides or Mn(III,IV) (hydr)oxides, can also be accomplished. The mechanism by which microbial cells interact with the molecular lattice of minerals is yet to be fully understood. It is speculated that structural or chemical defects, or points in the solid where energy has been perturbed, can serve as regions of reactivity or possibly access sites for organisms (Fredrickson and Zachara, 2008).

Nonenzymatic, extracellular strategies for moving electrons from inside the cell to the outside in electron-transfer processes have been observed. One such strategy is the use of a protein on the cell wall surface that extends away from the cell or a molecule that passes between the cell and substrate when a bacterium lacks the c-type cytochrome necessary to reduce a metal internally (Rawlings, 2005; Gralnick and Newman, 2007; Dittrich and Luttge, 2008). When at a distance from a mineral, *Geobacter sulfurreducens* develops pili, or nanowires, which are localized to one side of the cell wall, and extend out to allow electron transfers to the mineral surface of Fe(III) (hydr)oxides (Reguera et al., 2005).

In addition to localizing proteins to the exterior of the outer membrane, another strategy bacteria use in extracellular respiration is to utilize small organic shuttles to transfer electrons to substrates at a distance from the cell. Quinones are ubiquitous structures found in nature and are principal constituents of soil organic matter (SOM). In the human body, coenzyme Q or ubiquinone is present in every cell, and the ubiquinone/ubiquinol redox couple plays a role in shuttling electrons between complex II and III of the mitochondrial electron transport chain during oxidative phosphorylation (Table 14.1; Banerjee, 2008). Ubiquinone also acts as a lipid-soluble antioxidant by accepting one electron and forming a stable radical anion semiquinone.

This same quinone structure is present in soils and natural waters as the primary abiotic electron-donating and accepting moiety of humic and fulvic acids in natural organic matter (Scott et al., 1998; Ratasuk and Nanny, 2007).

Phenolic groups are abundant in natural organic matter and are important in complexation reactions with metals. Phenolic groups can be biologically oxidized by the enzymes phenolase and laccase to produce quinones (Tan, 2003). Converse to this oxidation, a one-electron transfer to quinone forms the same, highly reactive intermediate semiquinone as with ubiquinone and then the second electron transfer forms hydroquinone (Larson, 1997). Hydroquinone is then capable of donating its two electrons in further reduction reactions, making the quinone–hydroquinone species a very dynamic redox constituent in soils. The natural reducing capacities of International Humic Substance Society (IHSS) humic acids were shown to increase several-fold following microbial reduction and were significant even under aerobic conditions (Peretyazhko and Sposito, 2006).

The electron-donating kinetics of dissolved organic matter in aquatic systems was shown to occur within the course of 1 day and capable of shuttling electrons to SO_4^{2-} and Fe(III) (Bauer et al., 2007).

Quinone moieties in natural organic matter can serve as TEAs in microbial respiration, cycling electrons from bacteria to mineral surfaces (Lovley et al., 1996; Bond and Lovley, 2002). Soil bacteria reduced the humic acid analog, anthraquinone-2,6-disulfonate (AQDS), which then shuttled electrons to reduce Fe(III) (Fredrickson et al., 1998; Kappler et al., 2004). The shuttling activity of AQDS was demonstrated further with *G. sulfurreducens* shuttling electrons to ferrihydrite in solution (Straub and Schink, 2003). This use of humic substances as a TEA may allow for more efficient respiration than directly using a mineral. The rate of electron transfer between reduced humic substances to ferrihydrite is approximately 27 times faster than the rate of *G. sulfurreducens* directly transferring electrons to ferrihydrite (Jiang and Kappler, 2008).

The biological reduction of electron shuttles, such as soluble humic acids, is important in soils, but abiotic reduction pathways also significantly contribute to the natural redox cycling of metals and nutrients. Lactic acid, tartaric acid, and citric acid were shown to reduce AQDS, which then shuttled electrons to enhance the reduction of Cr(VI) in solution (Brose and James, 2010). Low-molecular-weight organic acids, such as these, are produced naturally by microbial activity or plant root exudates and can be important reducing agents for quinone moieties in soils and soluble humic acids, thus further contributing to natural redox process in soils. Figure 14.2 illustrates the conceptual model of how citric acid reduces the electron shuttle AQDS to AH_2DS, which ultimately reduces Cr(VI) to Cr(III).

Electrons are in constant flux in soils, being transferred from electron donors to electron acceptors, often mediated by soil microorganisms, which results in metastable redox conditions in soils. Though thermodynamic equilibrium models may predict steady-state conditions, in reality, a dynamic nonequilibrium state is a more accurate representation of natural systems (Stumm and Morgan, 1996). Often, redox reactions in soils are moving

1.5 Citric acid → 1.5 3-Ketoglutarate

3e⁻

1.5 AQDS → 1.5 AH₂DS

3e⁻

Cr(III)(hydr)oxide ← Cr(VI)
FIGURE 14.2 The stoichiometric transfer of electrons from citric acid to AQDS, reducing it to the hydroquinone form AH_2DS, which ultimately reduces Cr(VI) to Cr(III).

toward equilibrium, but the reactions are constantly being perturbed by the influx and efflux of chemical species and soil biota, thus shifting activities and reestablishing new, partial equilibria. Dioxygen is the most ubiquitous electron acceptor in natural systems, when available, and the electron activity and type of microorganisms present in a soil depend, in part, on its presence.

Because a saturated soil restricts the diffusion of O_2, saturated soils allow for more electron flow to other electron acceptors, such as Fe(III) (hydr)oxides and SO_4^{2-} (Bartlett and James, 1993). When a soil becomes submerged, pe decreases, and the rate of decrease will be a function of easily oxidized SOM, temperature, time submerged, and nature of available electron acceptors (Sparks, 2003), which are also important metabolic requirements of soil microorganisms. Though soils host a variety of microorganisms using a diverse array of electron acceptors for respiration, such as Fe(III) (hydr)oxides in anoxic sediments, SOM is the dominant electron donor and can be fully oxidized to CO_2 (Lovley, 2000), or partially to organic acids. Aerobic microorganisms will thrive until O_2 is depleted, and then facultative and obligate anaerobic microorganisms will be the dominant biological mediators.

Bacteria and their electron-shuttling systems are widely used in remediation strategies for organic and inorganic pollutants. Humus and other quinone analogs were used in the reductive biotransformation of nitroaromatic compounds and to dechlorinate organic pollutants (Field et al., 2000; Becker, 2006). In the anaerobic oxidation of phenol and *p*-cresol, it was shown that the addition of the quinone analog AQDS diverted electrons from methanogenesis to quinone reduction, a more thermodynamically favorable reaction (Cervantes et al., 2000).

The bioremediation of metals, such as Cr(VI) and U(VI) has also proven to be an effective strategy for treating contaminated soils and groundwater (Gu and Chen, 2003; Nyman et al., 2007; Wu et al., 2007). The cell wall of *Arthrobacter oxydans* contains an acid-soluble protein with a positive charge, as shown by electrophoresis, capable of reducing Cr(VI) to an insoluble Cr(III) (hydr)oxide (Asatiani et al., 2004). Bacteria can transform Hg compounds to either less toxic or less bioavailable species. *Desulfovibrio desulfuricans* API strain degrades CH_3Hg^+ by producing H_2S that reacts with CH_3Hg^+ forming the insoluble species $(CH_3Hg)_2S$ (Hobman et al., 2000). The dissimilative reduction of Se(VI), a soluble, toxic form of Se, to the insoluble Se(0) by anaerobic bacteria in anoxic environments has important implications for the continued irrigation of seleniferous soils and industrial applications such as the production of pesticides and semiconductors (Oremland and Stolz, 2000).

As bacterial metabolic activities are continually studied, more ways will be discovered to apply the use of microorganisms to transform pollutants to less toxic or less bioavailable forms. The adaptation of bacteria to a wide variety of electron donors and acceptors provides almost unlimited application of biologically mediated redox reactions. Understanding how bacteria link the oxidation of electron donors to the reduction of electron acceptors will provide insight into further utilizing these mediated reactions to improve ecosystems and natural waters.

14.2 Methods and Procedures

14.2.1 Uses of pe–pH Thermodynamic Information

Values of log K derived from Gibbs free energy of formation data or kinetic evaluations of redox reactions provide tools for predicting if a reduction half-reaction coupled with an oxidation half-reaction will allow the spontaneous transfer of electrons from reductant to oxidant. Since soils are only metastable and highly heterogeneous in nature, such predictive capability is necessary to formulate hypotheses for many processes that may occur in the field, even if they require microbial catalysis or other coupled reactions to occur at ambient temperatures and pressures of soil–water–plant systems.

The reduction half-reactions listed in Table 14.1 are biological and abiotic species of N, O, Mn, Fe, S, C, various pollutants sensitive to redox conditions in soils and several reactions pertinent to the analysis or characterization of redox conditions. Within groups, the half-reactions are arranged in descending order of log K values, calculated as described above. These values are pe at pH = 0 when activities of oxidant and reductant are 1 and may be considered standard, reference pe values for the reactions (formal potentials). The pe values listed at pH 5 and 7 are calculated to represent typical activities of ions and partial pressures of gases in soil environments.

Higher log K or pe values indicate greater "ease of reduction" of an oxidant (left side of equation) to its reduced form than do lower values. This means that for predictive purposes, an oxidant in a particular reduction half-reaction is able to oxidize the reductant in another half-reaction with a lower pe, at a specified pH, as demonstrated quantitatively for the FeOOH–Fe^{2+} and SO_4^{2-}–H_2S couples. Another example shows Mn(III,IV) (hydr) oxides would be expected to oxidize $Cr(OH)_3$ to Cr(VI) at pH 5 since the range of pe values for reduction of Mn (12.8–16.7) is greater than that for Cr(VI) reduction (10.9). This has been demonstrated to occur in most field-moist soils in the pH range of 4–7 containing oxides of Mn(III,IV) (Bartlett and James, 1979; James and Bartlett, 1983). Conversely, these oxides would not be expected to oxidize N_2 to N_2O (pe at pH 5 = 22.9).

Even though the log K or pe for one reduction half-reaction is less than that for a second half-reaction, the reduced form in the first reaction may still be oxidized by the oxidized species in the second half-reaction (the reverse of the above concept). For example, the pe at pH 5 for reduction of CO_2 to $C_6H_{12}O_6$ is −5.9 and that for reduction of O_2 to H_2O is 15.6. Based on this difference, one would predict that reduction of O_2 to H_2O would be coupled to oxidation of $C_6H_{12}O_6$ to CO_2, and coupling oxidation of H_2O to O_2 with reduction of CO_2 to $C_6H_{12}O_6$ would not be thermodynamically probable. In fact, both respiration (the predicted reaction) and photosynthesis (the second, "improbable" reaction) occur together, and the balance of the two is responsible for the existence of the aerobic lifestyle and the persistence of SOM. Photosynthesis (represented simply as $CO_2 \rightarrow C_6H_{12}O_6$) is made possible by a complex series of coupled reactions that

make an overall thermodynamically improbable reaction occurring rapidly in sunlight.

Similarly, a reaction predicted to be thermodynamically probable may not occur at any appreciable rate under natural conditions. The pe for NO_3^- reduction to N_2 at pH 5 (14.3) is greater than that for $HCrO_4^-$ reduction to $Cr(OH)_3$ (10.9), but this NO_3^- oxidation of Cr(III) has not been demonstrated in soils or plants, probably because the reduction of NO_3^- requires enzymatic catalysis to lower the energy of activation at such a high pH.

The order of log K values for reduction half-reactions also has been used to predict the sequence of reduction reactions carried out by respiring soil microorganisms following saturation of a soil (Ponnamperuma, 1972). The descending order of preference (pe) for the electron acceptors at pH 7 (proportional to free energy derived from the reduction) is O_2–H_2O (13.6), NO_3^-–N_2 (11.9), MnO_2 –Mn^{2+} (8.8), $Fe(OH)_3$–Fe^{2+} (–1.2), SO_4^{2-}–H_2S (–3.5), and CO_2–CH_4 (–4.1). Heterotrophic bacteria are using organic compounds as the electron donors and their energy source (chemoorganoheterotrophs) in their respiration to produce CO_2 or organic acids (pe range at pH 7 of –8.7 to –3.1), so most of the organic compounds can be used throughout the reduction sequence following depletion of atmospheric O_2.

14.2.2 Use of pe–pH Diagrams

14.2.2.1 Oxygen Species

While the pe for reduction of O_2 to H_2O ranges from 20.8 at pH 0 to 13.6 at pH 7 (Table 14.1), the intermediates associated with one-electron transfers show a wide fluctuation in their oxidizing power (Equations 14.28 through 14.32), a property of O_2 that is pertinent to understanding the transition in soils from "aerobic" to "anaerobic" conditions. Anaerobic respiratory enzymes are typically produced when P_{O_2} reaches approximately 1% of atmospheric levels (0.0021 atm). The data in Table 14.2 also indicate that the pe for reduction of O_2 is relatively insensitive to the O_2 partial pressure in this range.

Ozone (O_3) and the hydroxyl free radical (HO•) are the most powerful oxidants among the oxygen species (Table 14.1), and the latter may be formed during stepwise, four-electron reduction of O_2 to O_2^-, H_2O_2, and H_2O (Fridovich, 1978; Equations 14.28 through 14.32). The high and low pe values for superoxide reduction to H_2O_2 and for superoxide oxidation to O_2 indicate that both a powerful oxidant and a powerful reductant agent are formed in the first of four, one-electron steps in the reduction of O_2 to H_2O. The enzyme superoxide dismutase scavenges superoxide in living cells using O_2 as the TEA (respiring aerobically), but relatively little is known about its reactivity in biological and chemical processes in soils that may be pertinent to our understanding of the formation of highly reduced components such as SOM and highly oxidized species such as NO_3^- that coexist in soil under non- or quasi-equilibrium conditions.

The wide range of reduction potentials for O_2 and its partially reduced intermediates, coupled with biological processes controlling the partial pressure of this gas in soil solution, create

TABLE 14.2 Sensitivity of Calculated pe at pH 0 to Variation in ΔG_f^o and Activities of Oxidant and Reductant in Selected Half-Reactions Pertinent to Soils

[a] Change in calculated pe resulting from a change in activity of the ox or red species (column 1 or 2) or resulting from use of a ΔG_f^o value that is 44 kJ mol^{-1} (10 kcal) different from the published value (first row, column 3 or 4).

conditions under which the O_2–H_2O system may rarely attain equilibrium. Therefore, only metastable conditions and a slow approach to chemical equilibrium characterize O_2 behavior, making thermodynamic predictions difficult for aerobic soils (Bartlett, 1981).

14.2.2.2 Nitrogen Species

Most reduction reactions of N species (Table 14.1) are not reversible, are biologically mediated, and therefore are not well defined by thermodynamic pe–pH relationships. The series of half-reactions composing the process of denitrification, though, is instructive in that it identifies the wide range in pe for reduction of each of the intermediates believed to form in the sequence of electron acceptors used by microbes:

$$NO_3^- \xrightarrow[(1)]{} NO_2^- \xrightarrow[(2)]{} NO \xrightarrow[(3)]{} N_2O \xrightarrow[(4)]{} N_2$$
Steps
Step (1) of the sequence occurs at pe values less than those for reduction of O_2 to H_2O, while those for steps (2), (3), and (4) are increasingly higher. The overall reduction of NO_3^- to N_2 is almost identical to that for the O_2–H_2O couple. The similar pe range for the O_2 and NO_3^- reduction intermediates indicates that denitrification and aerobic respiration may occur at the same time under certain conditions when organic C is used as the electron donor. They may not be mutually exclusive as predicted from log K values for the overall reactions, O_2 to H_2O and NO_3^- to N_2.

14.2.2.3 Manganese Oxide Species

Manganese exists in soils in the II+, III+, and IV+ oxidation states, and the latter two are most stable as oxides or oxyhydroxides. Trivalent Mn may exist as $Mn(H_2O)_6^{3+}$, especially if stabilized by ligands, such as pyrophosphate or citrate. The pe values (Table 14.1) predict that different oxidation states of Mn in Mn_3O_4, MnOOH, and MnO_2 affect the pe at which Mn^{2+} would be expected to form at pH 5 (pe values of 16.7, 14.4, and 12.8, respectively), but they are all similar at pH 7 (8.7, 8.4, and 8.8). The Mn^{3+}–Mn^{2+} couple indicates that at pH ≈ 5, Mn^{3+} is a powerful oxidant (pe 25.5) similar to superoxide (pe 22.6) if in equilibrium with Mn^{2+}. At pH ≈ 6.5, Mn^{3+} in equilibrium with MnO_2 is a powerful reductant similar to H_2 and again, superoxide. This predicted reducing energetics of Mn^{3+} may be pertinent to anaerobic soils that are exposed to O_2, and in which Mn^{2+} is oxidizing to form Mn(III,IV) (hydr)oxides via Mn^{3+}. In oxidized soils containing MnO_2, flooding and the process of becoming reduced may produce Mn^{3+}, which is a powerful reducing agent. The trivalent Mn species may be ephemeral intermediates in such processes at redox interfaces, such as in the rhizosphere of plant roots or between the vadose zone and groundwater.

Since many Mn(III,IV) (hydr)oxides are nonstoichiometric and no compound with the exact composition of MnO_2 is known (Arndt, 1981), predictions of their redox properties as a function of mineralogy or oxidation state in heterogeneous soils may be hard to formulate. Despite the uncertainty of thermodynamic predictions for the redox behavior of Mn, the chemistry of this element is pertinent to a number of processes governing speciation and oxidation state of trace elements and pollutants found in soils (Bartlett and Ross, 2005). The pe–pH data indicate that oxides of Mn may oxidize Pu(III) to Pu(IV), V(III) to V(V), As(III) to As(V), Se(IV) to Se(VI), N(III) to N(V), and Cr(III) to Cr(VI) since the pe for each of these couples falls below that for Mn oxides (Table 14.1). The oxidations of Pu(III), As(III), Se(IV), N(III), and Cr(III) all have been demonstrated to occur in soils containing Mn(III,IV) (hydr)oxides or by synthetic Mn(III,IV) (hydr)oxides (Bartlett and James, 1979; Amacher and Baker, 1981; Bartlett, 1981; Moore et al., 1990; Blaylock and James, 1994).

The instability of Mn^{3+} and its ability to dismutate, similar to H_2O_2 and superoxide, mean that kinetic constraints and very low steady-state concentrations in soil solution may be particularly important in understanding the redox behavior of Mn in soils undergoing transitions between anaerobic and aerobic conditions. The kinetic lability of these species is poorly understood and new knowledge could contribute significantly to predictions of bioavailability and toxicity of numerous plant nutrients and pollutants in a range of soil types from rice paddies and wetlands to well-drained agricultural and forest soils.

14.2.2.4 Iron Species

While predictions of redox behavior of Fe(II) and Fe(III) species indicate that they fall below most Mn(III,IV) (hydr)oxide species (lower pe values and less free energy released per equivalent upon reduction), intermediate hydrolysis products, such as $Fe(OH)_2^+$, theoretically can oxidize Cr(III) to Cr(VI) at pH values <4 (Table 14.1). In addition, thermodynamically more stable complexation of Fe^{3+} by organic and inorganic ligands such as OH^-, relative to complexation of Fe^{2+}, lowers the pe at which Fe^{3+} is reduced to Fe^{2+}. These Fe(II)–Fe(III)-ligand reduction potentials are similar to those of Fe(III) (hydr)oxides in the pH range 5–7 (Table 14.1). This phenomenon suggests that Fe(II)–Fe(III)-ligand systems create Fe(II) species that are more powerful reductants than hexaquo Fe^{2+} if the Fe(III)-ligand complex is more thermodynamically stable than the Fe(II)-ligand complex. Conversely, if the complex with Fe(II) is more stable than that with Fe(III) (e.g., with phenanthroline), the Fe(II) becomes a less powerful reductant than hexaquo Fe^{2+}. This may explain the ability of a Fe(II,III) system to act as a cofactor in enzymes involved in redox processes, such as peroxidases and superoxide dismutases. These enzymes reduce or dismutate H_2O_2 and superoxide. The application of such concepts to abiotic redox processes in soils remains a key area for future research.

14.2.2.5 Carbon and Sulfur Species

Reduced forms of C and S are normally viewed as reductants in soils, either in abiotic or biological processes. Thermodynamic predictions support this idea for carbohydrates produced in photosynthesis, CH_4 from methanogenesis, and H_2S from reduction of SO_4^{2-} (Table 14.1). The reduction reactions of *o*- and *p*-quinone, suggest that these compounds may be reduced at higher pe values than are CO_2 and SO_4^{2-}. These pe values, however, coincide with the MnO_2/Mn^{3+} couple at pH 7, suggesting that Mn^{3+} may act as a reducing agent for certain organic species in near neutral soils. The coupling of reduction of the organic species with oxidation of Mn may result in formation of free radical species. This is pertinent to understanding the formation and persistence of SOM in high pH soils that may contain reactive forms of Mn(III,IV) (hydr)oxides (Bartlett and Ross, 2005).

Reactions of H_2S and H_2Se are predicted to be similar with respect to SO_4^{2-} and SeO_3^{2-} formation (Table 14.1). While SeO_4^{2-} and SO_4^{2-} are similar chemically, the oxidation of SeO_3^{2-} to SeO_4^{2-} is predicted to occur at higher pe values than that of H_2S to SO_4^{2-} (Table 14.1). Blaylock and James (1994) observed that Mn(III,IV) (hydr)oxides in soils or in pure form will oxidize SeO_3^{2-} to SeO_4^{2-}, as predicted by thermodynamics. They also observed that adding reducing phenolic acids, such as gallic and ascorbic acids, actually enhanced this oxidation reaction of SeO_3^{2-}. They hypothesized that partial reduction of MnO_2

in soils converted the Mn(IV) (hydr)oxide into a Mn(III) (hydr)oxide or ion that is a more powerful oxidant for SeO_3^{2-} than is Mn(IV) oxide. Such a hypothesis is supported by the relative oxidizing power of MnO_2, $MnOOH$, and Mn_3O_4, where the latter two oxides contain Mn(III) (Table 14.1).

14.2.3 Measurement of Soil Redox and Acid–Base Status

The most common method for quantifying electron activity of soils and natural waters is to measure the potential difference between a Pt indicator electrode and a calomel or Ag/AgCl reference electrode, both connected to a voltmeter or a pH meter (Pearsall and Mortimer, 1939; Patrick and DeLaune, 1972; Rowell, 1981; Bricker, 1982; Patrick et al., 1996; Rabenhorst et al., 2009). In this method, the Pt electrode is presumed to be inert and does not react chemically while coming into equilibrium with electroactive species in soil solution and on soil colloids (Compton and Sanders, 1996). Figure 14.3 illustrates how a Pt electrode establishes an equilibrium condition with soil solution. When the electrode contacts the soil solution (and while coupled to a reference electrode), a tiny quantity of electrons jumps either from the soil solution to the electrode (when soil is more reduced than the electrode) or in the opposite direction when the soil solution is more oxidized. In the first case, the Pt electrode becomes more negative relative to the soil, and this lowers the voltage at the electrode–soil solution interface. In the second, the electrode surface and the potential become more positive.

A high input impedance ($\geq 20\,\text{m}\Omega$) is needed to obtain precise and accurate electrode potentials, because if current flows under low impedance, drift will be observed in the voltage readings (Rabenhorst et al., 2009), and redox reactions may take place at the electrode–soil solution interface. Such reactions may form interfering redox couples on the Pt metal (e.g., $Pt(OH)_2$–Pt or PtS–Pt; see Table 14.1). Commercially available pH meters typically have high input impedance, but inexpensive voltmeters that are sometimes used in field studies with multiple Pt electrodes do not.

Generally, Pt electrode measurements are only semiquantitative for assessments of redox status, especially of aerobic soils in the field (Whitfield, 1974; Bartlett, 1981; Grenthe et al., 1992; Hostettler, 1992; Grundl, 1994). Other methods that employ analysis of soil solution analytes indicative of redox status, along with thermodynamic half-reactions, as discussed above, may prove more reliable for calculating pe ranges for aerobic and anaerobic soil systems (Peiffer et al., 1992; Kludze et al., 1994; Lovley et al., 1994; Stumm and Morgan, 1996; Typrin, 1998).

14.2.3.1 Construction and Use of Pt Electrodes

Platinum and suitable reference electrodes are relatively easy and inexpensive to construct (Mueller et al., 1985; Farrell et al., 1991), but measurement technique may significantly alter measured voltages (Bartlett, 1981; Bricker, 1982; Matia et al., 1991). These researchers have described several aspects of electrode use and misuse with respect to the reliability of recorded voltages for natural systems. Comparisons have been made between H_2 and Eh measurements for redox status in a contaminated aquifer (Chapelle et al., 1996). Quantification of H_2 was more reliable than Eh measurements for identifying anoxic redox process, especially when considered with respect to electron acceptor availability. The limits and limitations of Eh measurements have been described for natural systems, especially with respect to how long the electrodes may be left in place in the soil or water (Mansfeldt, 1993; Norrström, 1994) and with respect to interpreting the Eh values obtained (Baas-Becking et al., 1960; Whitfield, 1974; Lindberg and Runnells, 1984; Yu, 1992). Platinum electrode systems also have been incorporated into potential-controlling systems for long-term laboratory studies (Patrick, 1966; Petrie et al., 1998).

14.2.3.2 Inadequacies of Pt Electrode Potentials

Assessing "electron activity" in soils relates strictly to an evaluation of the ability of the electron to be transferred, or do thermodynamic work, and not of its concentration or activity in soil solution, as can be defined for H^+. Because of the nature of the electron and its differences from H^+, a number of caveats must be described and recognized when evaluating Pt electrode potentials.

14.2.3.2.1 Dissolved Oxygen Status

While a stable potential can be obtained for a Pt-reference electrode pair immersed in an oxygenated soil suspension, this potential is unreliable as a measure of dissolved oxygen status (Bricker, 1982; Stumm and Morgan, 1996). The Pt surface may
FIGURE 14.3 The energy of electrons in ions in solution and in the Pt electrode. (Taken from Compton, R.G., and G.H.W. Sanders. 1996. Electrode potentials. Oxford Science Publications, Oxford, U.K. p. 4, Fig. 1.2.)

react with O_2 to form $Pt(OH)_2$ that develops a potential with elemental Pt with a pe of 9.6 at pH 7 (Table 14.1). In addition, the measurement may not be that of the O_2–H_2O couple but may be responding to O_2 reduction intermediates, such as H_2O_2 and superoxide (Bricker, 1982). In addition, predicted pe values are relatively insensitive to changes in dissolved O_2 between 0.21 and 0.0021 atm (Table 14.2), the range of O_2 partial pressures in which aerobic respiration occurs (Russell, 1973). For these reasons, Pt electrode potentials cannot be used reliably as a measure of redox status for aerobic soils, but empirical values for pe may be obtained for comparison purposes (Bartlett, 1981, 1998).

While more faith is placed in measurements of soil pH, it also should be considered an empirical measurement because of uncertainty about the form of the H^+ ion in colloidal environments and about the behavior of the glass electrode in such systems. For these reasons, both pe and pH measured with electrodes in soils may be very uncertain for accurate descriptions of the redox status of soil environments containing air-filled pores.

14.2.3.2.2 Irreversibility of Redox Couples

Many of the important redox processes involving C, H, N, O, and S (the "light" elements, relative to the "heavy" metals) are irreversible in the thermodynamic sense, and nonelectroactive gases and molecules may be consumed or formed. As a result, potentials generated by redox couples for these elements are difficult to obtain and interpret using a Pt electrode. In addition, many of these reactions do not reach true chemical equilibrium, and activities measured in soil solution may be kinetically constrained (Liu and Narasimhan, 1989). Since soil redox status is often set by "microbial potentials," as discussed earlier, consuming or producing compounds or ions containing one or more of these elements may render Pt electrode measurements inaccurate.

14.2.3.2.3 Mixed Potentials

Measured redox potentials in soils normally are governed by more than one redox couple ("mixed potentials"), and these couples usually are not at true chemical equilibrium. Therefore, thermodynamic interpretations of measured Pt electrode potentials in soil suspensions need to consider several couples, and analyses of soil solution concentrations of redox active species may be indicative of the couples controlling the potential at the Pt surface (Typrin, 1998). For example, a Fe^{2+}–Fe^{3+} couple at activities greater than 10^{-5} M generates sufficient anodic and cathodic currents to obtain a measurable voltage for the system, and this may coexist with the relatively nonelectroactive couple, O_2–H_2O in heterogeneous soils.

The establishment of a measurable balance between the cathodic and anodic current at the Pt electrode at the point of zero applied voltage requires activities of $>10^{-5}$ M, a condition that may not exist for many redox active species of interest in soils. Activities $<10^{-6}$ M may be common, especially for certain plant nutrients and soil pollutants. For this reason, application of measured Pt electrode potentials to predicting soil composition may not be possible.

14.2.3.2.4 Coupling of pH and pe

Based on the complementary nature of pH and pe (Stumm and Morgan, 1996) summing pe + pH to describe log K for soils is possible theoretically, as described above. Due to the fact that the Pt electrode responds to pH (almost in Nernstian fashion) as well as to electron activity, pH should always be measured and reported with pe. The negative slopes of the pe–pH relationships (Figure 14.1) of many of the reduction half-reactions also indicate that the energy change associated with a particular reduction reaction decreases with increasing pH. Therefore, an Eh measurement cannot be used to predict the presence of a particular redox couple unless pH is known. Since higher pe values at lower pHs correspond to larger releases of free energy, reduction reactions are expected to be more likely to occur at lower pH. That is, such systems are ones in which "reduction is favored." In contrast, loss of electrons from reductants of a particular couple is favored at higher pH, or the system is more "prone to oxidation."

14.2.4 Proposed Alternative Strategies for More Accurate Measurement of Soil Redox Status

14.2.4.1 Using Electrochemical Relations in Reverse

Given the uncertainty associated with measured Pt electrode potentials in soils to quantify Eh or pe, actual measurements of reductant and oxidant activities, along with a reliable pH measurement, may be a better approach (Stumm and Morgan, 1996; Typrin, 1998). The activities are substituted into appropriate half-reactions relating pe and pH, and pe is thereby obtained by calculation.

As shown in Table 14.2, the pe predicted by such a technique will be inaccurate to different degrees for different half-reactions. For example, an error of two log units for H_2S or O_2 partial pressures will only produce errors of 0.3–0.5 pe units. In contrast, similar errors in measurement of Mn^{2+} or Fe^{2+} will result in pe errors of 1.0–3.0 pe units. Since Mn and Fe are relatively easy to measure accurately by atomic absorption or colorimetric methods and mineralogy of associated oxides can be made with infrared or x-ray techniques, assessing pe for Mn and Fe oxide-dominated systems could be reliable. Detailed research is needed to prove this hypothesis. In contrast, dissolved gases are harder to measure accurately, and qualitative estimates may be sufficient to obtain accurate evaluations of pe.

If calculated pe values obtained with this "reverse electrochemical technique" are equal for two different reduction half-reactions, then chemical equilibrium may be assumed to exist. If the pe values are unequal, then disequilibrium and a metastable, kinetically limited soil system probably exists. This latter condition is common in soils due to spatial heterogeneity of soil solution, oxide mineralogy, organic matter reactivity, and microbial controls on key reactions. New thinking and hands-on research are needed to provide new ideas for evaluation of the "electron activity" for soils by this combination of analytical and thermodynamic approaches. A key to its accuracy is knowing what

redox couples are contributing to the electron activity, assumed to exist as a quantifiable parameter at chemical equilibrium.

14.2.4.2 Redox Ranges for Empirical pe Values

These limitations to assessing soil pe based on Pt electrode and reverse electrochemical methods indicate that our sense of accuracy for soil redox status must be modified. If we surrender in our efforts to conceptualize and operationally define soil redox status, we will have lost a challenging scientific crusade. This means that while new ideas are being developed, we accept a lack of knowledge of pe values more accurate than ranges bracketed by whole numbers.

Liu and Narasimhan (1989) have described "redox zones" in which a range in Eh or pe defines an electron activity condition. The oxygen–nitrogen range is defined by Eh values of +250 to +100 mV, the iron range is +100 to 0.0 mV, the sulfate range is 0.0 to −200 mV, and that for methane–hydrogen is defined at < −200 mV. Sposito (1989) proposed "oxic" soils as those with pe > 7, "suboxic" ones in the range of pe between +2 and +7. and "anoxic" soils with pe < +2; all at pH 7. These ranges correspond roughly to redox control by oxygen–nitrogen, manganese–iron, and sulfur couples.

Berner (1981) proposed categories for redox named "oxic, postoxic, sulfidic, and methanic" controlled by transformations of oxygen/nitrogen, iron, sulfur, and methane–hydrogen, respectively. James (1989) has proposed these names be assigned to ranges in EMpe (empirical pe; Bartlett, 1981, 1998) of +7 to +13, +2 to +7, −2 to +2, and −6 to −2 (at pH 7). The appropriateness of these categories and names will require further evaluation of new operational definitions for the concept of "redox status" in soils.

Bartlett and James (1995) proposed a new system for categorizing soil redox status using chemical field tests such as tetramethylbenzidine for Mn status, Cr oxidation–reduction reactions, Fe speciation, sulfide levels, and pH. They proposed the following categories: superoxic, manoxic, suboxic, redoxic, anoxic, and sulfidic, which relate to electron lability in heterogeneous soil systems under field conditions. Bartlett (1998) has refined this system of redox classification and applied it to interfacial processes in soils pertinent to wetlands, hydric soils, and other soil–water systems containing contrasting zones of redox status.

14.2.4.3 Use of "Indicator of Reduction in Soils" (IRIS) Tubes

A novel method for assessing whether or not a soil may become reducing for Fe(III) (hydr)oxides to Fe(II) is to coat 21 mm, polyvinyl chloride (PVC) tubes with paints made from Fe(III) (hydr) oxide suspensions of known mineralogy. The coated tubes are placed in soil columns in the laboratory or in the field, and after a period of incubation, the extent of removal of Fe(III) from the tubes by reduction to Fe(II) is quantified by image processing (Rabenhorst et al., 2008 and references therein). Such in situ, empirical methods may prove useful in delineating wetlands, hydric soils, and the extent of reducing conditions for Fe(III) under various soils conditions.

14.3 Applications of Redox Methods and Concepts to Ecological, Engineered, and Agricultural Soil Systems

The principles and theories of oxidation–reduction processes in soils, and methods for defining them operationally, have many applications that relate to root–soil interactions in the rhizosphere, to pollutant oxidation state in and remediation of contaminated soils, to nutrient management and soil fertility in agricultural and wild ecosystems, to the role of soils in global C balances affecting the earth's climate, to the study of wetlands and hydric soils, and to understanding groundwater chemical composition at the interface with surface waters. A brief discussion of each of these applications follows, coupled to specific examples.

14.3.1 Rhizosphere Processes

Root exudates (rhizodeposition), especially those containing C compounds, are key constituents that influence microbial metabolism and chemical processes in the rhizosphere (Jones et al., 2009). These exudates may be the result of cell sloughing, establishment and maintenance of microsymbionts, gaseous loss (e.g., O_2 and CO_2), and mucilage production. Carbon compounds typically act as electron donors (and in the case of quinone functional groups as electron acceptors) for heterotrophic microbes, and HCO_3^- acts as the C source for autotrophs.

The diffusion of O_2 from the atmosphere through aerenchyma tissue formed in stems and roots in response to the development of anaerobic soil conditions favors the formation of oxidized rhizospheres in plants adapted to grow in anaerobic soils. Examples are rice paddies, freshwater and tidal wetlands, and other poorly drained soils (Marschner, 1995). In plants poorly adapted to growth in anaerobic soils, redox changes related to denitrification, reductive dissolution of Mn(III,IV) (hydr)oxides and Fe(III) (hydr)oxides, sulfate reduction, and methanogenesis can significantly affect plant growth, the maintenance of a symbiotic relationship with N_2-fixing bacteria and mycorrhizal fungi (Marschner, 1995).

The formation of the products of organic matter decomposition and fermentation of glucose to lactate or ethanol can affect rhizosphere chemistry and microbial activity. Formation of ethylene, volatile fatty acids, and phenolic compounds activity affects vascular tissue conductivity and root growth (Marschner, 1995). Ethylene production in root tissues in response to water logging is responsible for the formation of aerenchyma tissue in plants tolerant of anaerobic soil conditions.

The rhizosphere is a soil environment that is hard to study in situ but one that is critically important in plant nutrition, soil fertility, plant pathology, soil biochemistry, microbial ecology, and pedology. The August, 2009 issue of *Plant and Soil* comprises 21 articles dedicated to reviewing current knowledge of rhizosphere processes, many of which are redox based (Dessaux et al., 2009).

14.3.2 Soil Remediation and Pollutant Speciation

In recent years, much emphasis has been placed on the remediation of soils contaminated with organic or inorganic industrial waste products (Clapp et al., 2001). Examples of these contaminants are synthetic organic chemicals, such as dense nonaqueous phase liquids (DNAPLs); benzene, toluene, ethylbenzene, and xylenes (BTEX); and pesticides (herbicides, insecticides, and fungicides) (Schwarzenbach et al., 1993). The oxidation or reduction of functional groups, aliphatic chains, and aromatic rings results in changes in solubility and toxicity (Schwarzenbach et al., 1993; Clapp et al., 2001).

The oxidation state of contaminant metals and metalloids can be transformed through microbiological or chemical redox processes. Such redox-based remediation changes their speciation, solubility, bioavailability, and toxicity (Sauvé and Parker, 2005). In such cases, the total, unspeciated concentration of the element in question remains the same; only the oxidation state is changed. In these cases, the development of new methods for speciation and fractionation (Sauvé and Parker, 2005) based on oxidation state of the element has contributed to novel methods for remediation that do not involve removal of the element from the soil and that allow novel, in situ methods of remediation (James, 1996).

An example of an ongoing remediation-by-reduction are soils contaminated with chromate [Cr(VI)] from industrial plating operations and chromite ore processing residue (James, 1996). In situ or _ex situ_ conversion of toxic, soluble Cr(VI) to much less toxic and insoluble Cr(III) species has been effective in laboratory, pilot, and field-scale studies. Methods studied have included elemental Fe in permeable reactive barriers (PRBs; Rivero-Huguet and Marshall, 2009), steel wool (James, 1994), ascorbic acid (Xu et al., 2005), animal manures (Bartlett and Kimble, 1975), polysulfides (Graham et al., 2005), and $FeSO_4$ (Geelhoed et al., 2003). Central to the acceptance of these methods by government regulatory agencies has been the refinement of an analytical method for soils that selectively dissolves Cr(VI) from the solid matrix without reducing it and without method-induced oxidation of Cr(III) in the soil (Vitale et al., 1997).

14.3.3 Soil Fertility and Nutrient Cycling

Redox transformations are central to the biological controls of the N cycle, including N_2 fixation (N_2 to NH_4^+), nitrification (NH_4^+ to NO_3^-), denitrification (NO_3^- to N_2O and N_2). These processes govern the speciation of N in all ecosystems, whether in wild biomes, engineered soils, or domesticated agricultural ecosystems. Redox processes also govern speciation, bioavailability, and solubility of Mn, Fe, C and S, cofactors in many of the enzymes that catalyzed these N redox changes (Sylvia et al., 2005).

In soils and natural waters, high levels of P contribute to the growth of cyanobacteria and are therefore a concern related to eutrophication of freshwaters (Howarth, 1988). The oxidation state under ambient biological temperatures and pressures remains V+, but reduction of Fe(III) (hydr)oxides and the oxidation of Fe(II) control, in complex ways, the presence of an important sorbent for orthophosphate in soils ($H_2PO_4^-$ and HPO_4^{2-}, the dominant inorganic forms of P between pH 4 and 9; Young and Ross, 2001; Sims and Pierzynski, 2005).

14.3.4 Soil Organic C Dynamics and Climate Change

The oxidation state of C varies from IV– to IV+ in natural environments, and enzymatic processes govern transformations among them. Examples of the classes of C compounds representing the range of oxidation states are alkanes (IV– in methane, CH_4), alcohols (II– in methanol, CH_3OH), aldehydes (0 in formaldehyde or general representations of SOM, CH_2O), carboxylic acids (II+ in formic acid, HCOOH, i.e., hydrated CO), and carbon dioxide (IV+ in CO_2; and when hydrated as H_2CO_3, HCO_3^-, and CO_3^{2-}, depending on pH). The speciation of C in soils is governed by myriad anabolic and catabolic processes in cells (Clapp et al., 2005; Table 14.3).

The knowledge of C speciation and the reactions governing it are central to many contemporary environmental, engineering, and agricultural concerns. Greenhouse gas and particulate releases into the atmosphere (CO_2, CH_4, black C and other C-rich particulates) has encouraged research on C sequestration related to balances between methanogenesis and methanotrophy (Sylvia et al., 2005). Concern about climate change due to greenhouse gas releases is linked to the kinetics of formation and degradation of SOM and to effects of tillage practices and plant and animal waste decomposition dynamics (Ussiri and Lal, 2009). Balances between sources of SOM (via photosynthesis and oxidation polymerization processes) and its decomposition to simple organic acids and CO_2 are keys to how soils may sequester organic C.

Clapp et al. (2005) provide an encyclopedic treatise on SOM, its structure, reactions, and roles in soils as a base for understanding organic matter and C dynamics. Lal (1999) provides a brief description, with examples, of the role of soils in the greenhouse effect. He includes relevant information on greenhouse emissions, with particular reference to rice paddies and organic soils. Falkowski et al. (2008) provide excellent perspective on the microbial redox processes that govern nonequilibrium biological systems, using what they call "nanobiological machines." They also describe how redox processes integrate sediments, water, and the atmosphere through interconnected, biologically mediated cycles for H, C, N, O, S, and Fe.

14.3.5 Wetland Delineation and Function

The delineation and redox-based functioning of freshwater and tidal wetlands (and their constituent hydric soils) are current challenges as a result of increasing interest in preventing loss of wetlands due to human development and sea level rise linked to global climate change and crustal subsidence (Hurt and Vasilas, 2006).

TABLE 14.3 Reduction Half-Reactions for Environmentally Relevant Species

Species		Equations	E^o (V)	Log K	ΔG_r^o (kJ/eq)
A	γ-MnOOH	γ-MnOOH + e^- + 3H^+ → Mn^{2+} + 2H_2O	1.50	25.4	−145.0
B	CrO_4^{2-}	1/3CrO_4^{2-} + e^- + 5/3H^+ → 1/3$Cr(OH)_3$ + 1/3H_2O	1.24	21.0	−119.9
C	MnO_2	1/2MnO_2 + e^- + 2H^+ → 1/2Mn^{2+} + H_2O	1.23	20.8	−118.8
D	$HCrO_4^-$	1/3$HCrO_4^-$ + e^- + 4/3H^+ → 1/3$Cr(OH)_3$ + 1/3H_2O	1.11	18.9	−107.9
E	AQDS	1/2AQDS + e^- + H^+ → 1/2AH_2DS	0.22	3.9	−22.3
F	Lactate	½Pyruvate + e^- + H^+ → 1/2lactate	0.23	3.9	−22.3
G	CH_2O	1/4CO_2 + e^- + H^+ → 1/4CH_2O + 1/4H_2O	−0.07	−1.2	6.9
Examples					
γ-MnOOH reduction by AH_2DS (A and E)				21.5	−122.8
$HCrO_4^-$ reduction by CH_2O (D and G)				20.1	−114.8
$HCrO_4^-$ reduction by lactate (D and F)				15.0	−85.7
$HCrO_4^-$ reduction by AH_2DS (D and E)				15.0	−85.7
$Cr(OH)_3$ oxidation by γ-MnOOH (A and D)				6.5	−37.1
AQDS reduction by CH_2O (E and G)				5.1	−29.1
AQDS reduction by lactate (E and F)				0.0	0.0

Chemical Rubber Co., Cleveland, OH.

These reactions can be combined to form redox reactions, many of which are energetically favorable as indicated by negative G_r values in the given examples.

The definition of hydric soils (Hurt and Vasilas, 2006) and wetlands are linked to redox conditions and dynamics associated with the position and fluctuations of the water table. A so-called technical standard for defining wetlands is based on Eh and pH measurements associated with the oxidation and reduction of Fe(II,III) (Rabenhorst and Castenson, 2005; Hurt and Vasilas, 2006; NTCHS, 2007). Recent research on IRIS tubes and the concept of "biological zero" have contributed new methods and conceptual thinking on this technical standard and how to define a wetland (Rabenhorst, 2005; Rabenhorst et al., 2008).

The chemistry of tidal marshes that are diurnally inundated with SO_4^{2-}-rich seawater leads to the accumulation of numerous iron sulfide minerals, including iron monosulfides (e.g., FeS) and pyrite (FeS_2) (Rabenhorst and James, 1992). In addition, the dynamics of organic C accumulation, methanaogenesis and methane oxidation are important applications of redox concepts because of the importance of CH_4 as a greenhouse gas (Liverman, 2007).

14.3.6 Riparian Soil-Vegetation Systems and Groundwater Nitrate Concentrations

Redox transformations of NO_3^- in groundwater have been major societal concerns due to the potential for eutrophication of natural waters, especially of by non-N_2 fixing, green algae in saline waters of estuaries, such as the Chesapeake Bay of the Coastal Plain of the United States (James et al., 1991). The reduction of N in NO_3^- (oxidation state V+) to N_2O (oxidation state I+) and N_2 (oxidation state 0) via denitrification in riparian ecosystems has been extensively studied (Lowrance et al., 1984; Peterjohn and Correll, 1984; Allan et al., 2008). The role of trees, understory vegetation, and planted grasses in riparian ecosystems has shown that black locust trees (*Pseudoacacia* spp.) act as a source of NO_3^- in groundwater that occurs following N_2 fixation, NH_4^+ release into the soil, and nitrification. When black locust trees were cut and replaced with planted tall fescue, NO_3^- concentrations in groundwater beneath the riparian zones decreased, whereas when non-leguminous trees (red oak, loblolly pine, and sassafras) were cut, NO_3^- concentrations increased. These results demonstrated the important roles played by vegetation–microbe–soil–groundwater interactions affecting N speciation (James et al., 1991).

14.4 Earlier Reviews and Prescient Work on Oxidation–Reduction Processes in Soils

There are numerous general reviews and examples of redox measurements, processes, applications, and data in soils and natural waters. Interested readers are referred to the following sources: Lindsay (1979), Buxton et al. (1988), Neta et al. (1988), Wardman (1989), Sawyer (1991), Bartlett and James (1993), Schwarzenbach et al. (1993), Helz et al. (1994), Blough and Zepp (1995), Compton and Sanders (1996), Stumm and Morgan (1996), Bartlett (1998).

Bartlett and Ross (2005) provide novel and heuristic ideas surrounding a central role played by Mn in soil redox processes, including formation of humic compounds, free radical reactions, nutrient cycling, rhizosphere chemistry, photochemistry, and wetlands. Other chapters in this book tie in soil acidity, chemical kinetics, and other topics related to oxidation–reduction.

Extensive redox-based research conducted by the late William Patrick and coworkers at the Wetland Biogeochemistry Institute at Louisiana State University (Baton Rouge, LA) has been central to much of current knowledge related to Eh and pH as master variable controlling the chemistry and biochemistry of tidal marshes and freshwater wetlands.

Remarkable, almost prescient, insight is provided in several references on electron activity and its measurement by the Pt electrode in the first four decades of the twentieth century following the discovery of the electron in 1897 (Gillespie, 1920; Willis, 1932; Pearsall and Mortimer, 1939). These researchers linked thermodynamic theory, biological processes in soils, and applications of redox chemistry to societal needs of their times—an accomplishment that can serve as a guide for future studies on the elusive electron in soil environments. Research and teaching related to oxidation–reduction processes in myriad soil environments remains a vital and dynamic field of study with many applications for future soil chemists and environmental scientists interested in addressing complex biological and chemical systems.

15.1 Nature of Soil Colloids

15.1.1 Significance of Colloidal Phenomena

The importance of colloids in soil science has been appreciated for many years. However, recent understanding that organic and inorganic contaminants are often transported via colloidal particles has increased interest in colloid science. Essentially, all chemicals and individual species are to some extent reactive with soils, including species such as chloride ions, which undergo repulsion from negatively charged surfaces. With few exceptions, soil chemistry is primarily the chemistry of colloids and surfaces. The primary importance of colloids in soil science stems from their surface reactivity and charge characteristics. The overwhelming majority of surface area and electrostatic charge in a soil resides in the less than 1 μm size fraction with particles with radii between 20 and 1000 nm constituting the major part of the soil surface area (Borkovec et al., 1993). A significant fraction of reactive soil colloidal material falls within the <100 nm size range and thus is relevant to the growing interest in the properties and behavior of nanoparticles. Furthermore, soil is often the ultimate repository for anthropogenic nanomaterials of environmental concern (Hochella, 2008; Theng and Yuan, 2008; Waychunas and Zhang, 2008). The unique aspects of "nanoscience" as a discipline separate from colloid science reflect deviations in material properties in the nanoparticle size range, especially for materials <10 nm, and in many cases the lack of a natural bulk analog in the larger size fractions, for example, ferrihydrite (Hochella, 2008; Waychunas and Zhang, 2008).

Characterizations of size, shape, surface area, surface charge density, and changes in surface charge are required for understanding the processes of adsorption, flocculation, dispersion, and transport in soils and the resultant changes in soil hydraulic properties, as well as chemical migration. Since the major part of the surface area is in the colloidal fraction of the soil, almost all surface-controlled processes including adsorption reactions, nucleation, precipitation, and dissolution involve colloids. Colloids are reactive not only because of their total surface area but also because of enhanced reactivity related to rough surfaces and highly energetic sites, as well as the effects of electrostatic charge. Colloid charge is associated with substitution of lower charge cations for those of higher charge in the mineral lattice (which results in a net permanent charge) as well as surface charge associated with broken bonds. The charge associated with broken bonds is characterized as variable charge in as much as the solution influences the surface speciation (Chapter 16). In addition to these chemical processes, colloids are mobile in soils and thus not only affect the chemical transport of otherwise immobile chemicals but also exert a strong influence on soil hydraulic properties.

15.1.2 Types of Soil Colloids

Colloidal particles are defined as having an equivalent spherical radius smaller than 1 μm (van Olphen, 1977). A homogeneous dispersion of colloidal particles in a liquid is called a colloidal dispersion. If the particles are large and settle rapidly, the dispersion is called a suspension. A colloidal dispersion is defined as a system where particles of colloidal dimensions are dispersed in a continuous phase of a different composition (van Olphen, 1977).

15.1.2.1 Oxides

Oxides, including hydroxides and oxyhydroxides, are ubiquitous constituents of soils, occurring as both discrete particles and as coatings on other soil surfaces. Oxide minerals that are commonly found in the soil clay fraction are discussed in Chapter 22.

Hydroxylation of oxide minerals can either be structural and/or occur by chemisorption of water in an aqueous medium (Schwertmann and Taylor, 1977). Edge hydroxyl groups on oxides and clay minerals represent the most abundant and reactive surface functional groups in soils (Sposito, 1984). Any one type of oxide mineral contains various groups of surface hydroxyls that are distinguishable by crystal plane location and/or extent of coordination to the cations of the bulk structure. However, as a simplification, it is often assumed that each oxide mineral has a single set of homogeneous reactive functional groups. Surface hydroxyl groups on most oxide minerals are amphoteric, exhibiting positive charge at low pH and negative charge at high pH. For this reason, oxide minerals are often referred to as variable charge soil minerals. Table 15.1 provides densities of surface hydroxyl groups for some common oxide minerals in soils.

Boehmite and gibbsite are the only crystalline Al oxides common in soils. Aluminum oxides are the products of intense weathering of aluminosilicate minerals and are most abundant in tropical soils. Gibbsite can also be found in volcanic ash soils of humid regions (Brown et al., 1978). Noncrystalline Al oxides, which have similar structure and chemical characteristics but smaller particle size than crystalline varieties, often dominate the chemical reactions with anions in soils (Hsu, 1977). Aluminum oxides play an important role in ion adsorption, stabilization of soil aggregates, and flocculation of soil particles.

Iron oxides are found in most soils and provide soil horizons with their red, yellow, and brown colors (Brown et al., 1978). Most iron oxides are the weathering products of iron-containing silicates. Goethite, which is the most common Fe oxide in temperate, subtropical, and tropical soils, is usually thermodynamically the most stable (Schwertmann and Taylor, 1977). Soil goethites are usually fine grained and contain appreciable substituted Al. Lepidocrocite is a minor constituent of waterlogged temperate soils undergoing alternating oxidizing and reducing conditions, whereas hematite is a common soil mineral that can

be inherited from parent materials or formed pedogenically in warm climatic regions (Brown et al., 1978). The two magnetic Fe minerals, magnetite and maghemite, occur in soils; the former is inherited from parent rock, while the latter is formed pedogenically in highly weathered soils (Brown et al., 1978). Ferrihydrites are poorly crystalline, have indefinite composition, and occur as very small particles with high surface area (Schwertmann and Taylor, 1977). Ilmenite is an uncommon mineral usually inherited from igneous or metamorphic parent rocks (Brown et al., 1978). Iron oxides play an important role in ion adsorption and in aggregation and cementation of soil particles.

Manganese oxides occur widely in soils as minor constituents, mainly as dark coatings on particle surfaces. Manganese oxides are chemically complex, existing as a continuous range of compositions between MnO and MnO_2 (Brown et al., 1978). Birnessite, vernadite, lithiophorite, and hollandite are the most common crystalline manganese minerals in soils (McKenzie, 1989). Birnessite occurs in both acid and alkaline soils, while lithiophorite occurs mainly in neutral to acid soils (Brown et al., 1978). These oxides supply Mn for plant nutrition. Manganese oxides exhibit a strong adsorption capacity for metal cations, especially copper, due to their pH-dependent charge, small particle size, and large surface area (McKenzie, 1989).

Rutile and anatase are the common titanium oxides occurring in soils. Rutile is a high-temperature form occurring in igneous and metamorphic rocks (Hutton, 1977). Anatase is a low-temperature form occurring as an alteration product of titanium containing minerals such as ilmenite and is much less abundant than rutile (Brown et al., 1978). Titanium oxides are present in both the coarse and fine fractions of soils and are very insoluble (Hutton, 1977).

Quartz is not only the most abundant silicon oxide but also the most abundant mineral in most soils. Most quartz is found predominantly in the sand, silt, and coarse clay fractions of soils (Wilding et al., 1977). Silicon oxides are generally considered inert having a small surface area and little surface charge.

15.1.2.2 Clay Minerals

The clay fraction of most soils is dominated by various layer silicate clay minerals. Layer silicate clay minerals are classified as 1:1 where each layer consists of one tetrahedral silica sheet and one octahedral alumina sheet, 2:1 where each layer consists of one octahedral sheet sandwiched between two tetrahedral sheets, or 2:1:1 where a metal hydroxide sheet is sandwiched between the 2:1 layers. Layer silicate minerals common in soils are discussed in Chapter 21. A discussion of silicate structures is provided by Schulze (2002).

Layer silicate clay minerals are characterized by isomorphic substitution of lower valence cations in either or both the tetrahedral and the octahedral sheets. This excess of negative charge is balanced by other cations, either inside the crystal or on the external surfaces (McBride, 1994). Layer charge is an electrostatic charge balanced outside of the structural unit and determines the strength and type of bonding occurring between the basal planes. Charge arising from isomorphic substitution is

TABLE 15.1 Densities of Surface Hydroxyl Groups on Oxide Minerals

Solid	Site Density Range (Sites nm^{-2})
Gibbsite	2–12
Goethite	2.6–16.8
Hematite	5–22
Ferrihydrite	1.1–10.1
MnO_2	6.2
TiO_2	2–12
Amorphous SiO_2	4.5–12

called permanent charge because it is independent of solution pH. Layer silicate clay minerals also possess variable charge located at the broken edges of the particles. At the edges of the octahedral sheet, hydroxyl ions attached to Al cations are called aluminol groups. Similar to the hydroxyl groups on oxide minerals, aluminol groups are amphoteric. At the edges of the tetrahedral sheet, hydroxyl groups attached to Si cations are called silanol groups. Silanol groups do not undergo protonation, but dissociate and become negatively charged at high pH. Adsorbed cations on clay minerals balance both pH dependent and permanent charges. Table 15.2 provides charge characteristics and cation exchange capacities (CEC) for some common clay minerals in soils.

Kaolinite is one of the most widespread clay minerals in soils, being most abundant in soils of warm moist climates (Dixon, 1977); while halloysite is formed through acid weathering and in soils of volcanic origin. The halloysite structure is the same as the kaolinite structure but contains a sheet of water molecules between the layers. Both minerals have low colloidal activity, low surface area, and low CEC and anion exchange capacity (AEC) (Dixon, 1977). The CEC and AEC of the 1:1 minerals are predominantly pH dependent (McBride, 1994).

Micas are abundant in soils, occurring as primary minerals inherited from soil parent materials. Micas strongly retain interlayer potassium ions, rendering them nonexchangeable and reducing the CEC of these minerals. Through weathering, micas release K and provide an important natural source of this plant nutrient (Fanning and Keramidas, 1977). Illite is a secondary mineral that is less crystalline, contains less K, and contains more water than muscovite mica (McBride, 1994). Micas and illites are nonswelling minerals.

Smectites constitute an important group of 2:1 clay minerals. Members that are important in soils include montmorillonite, beidellite, and nontronite. Smectites are most significant in moderately weathered soils and have high colloidal activity and high surface area. Smectites are responsible for a large part of the CEC and the majority of the shrink/swell properties of smectitic soils (Borchardt, 1977).

Vermiculite is an important clay mineral in soils that is formed as an alteration product of muscovite and biotite micas (Douglas, 1977). Vermiculite is widely distributed and has a wide particle size range. Vermiculites contain hydrated magnesium cations that can be readily exchanged by K and ammonium ions, resulting in collapse of the clay layers and fixation of these nutrient ions. Vermiculites have high CEC and high surface area but exhibit limited swelling.

Chlorites are 2:1:1 layer silicates that occur extensively in soils. The hydroxide interlayer sheet is usually dominated either by brucite [Mg(OH)$_2$] or by gibbsite [Al(OH)$_3$]. This interlayer sheet restricts swelling, decreases effective surface area, and decreases effective CEC (McBride, 1994). Chlorites are nonswelling silicates.

15.1.2.3 Organic Matter

Soil organic matter (SOM) refers to the mixture of products resulting from microbial and chemical transformations of organic residues and is discussed in Chapter 11. An important component of SOM is called humus, a complex and microbially resistant mixture of amorphous and colloidal substances. These substances are the result of modifications of original tissues or synthesis by soil microorganisms. Humic substances are subdivided into humic acid, fulvic acid, and humin using a separation scheme based on solubility in strong acid and base (McBride, 1994). The structure and composition of humus are complex and incompletely known. The structure contains a variety of reactive functional groups including carboxyl R–COOH, phenol C$_6$H$_5$OH, alcohol R–CH$_2$OH, enol R–CH=CH–OH, ketone R–CO–R′, quinone O=C$_6$H$_4$=O, ether R–CH$_2$–O–CH$_2$–R′, and amino R–NH$_2$ (Stevenson, 1982). Humus is amorphous and highly colloidal; its surface area, ion adsorption, and CEC are greater than those of layer silicate clay minerals (McBride, 1994). The presence of humus usually promotes aggregation of soil particles.

15.1.3 Properties of Soil Colloids

15.1.3.1 Particle Size and Shape

Colloids in natural systems are characterized by a continuous particle size distribution (PSD; polydispersivity) of extreme complexity and diversity. Organisms, organic macromolecules, minerals, clays, oxides, and combinations of any of them constitute the colloidal fraction in soils. The distribution of shapes, densities, surface chemical properties, and chemical composition vary widely with size. Some fractions of the size spectrum may be living, and all particulates are subject to diverse physical, chemical, and biological processes that can alter size distribution, shape, or chemical composition (Kavanaugh and Leckie, 1980).

Colloids are dynamic particles, subject to constant alteration; the distribution of particle sizes in natural systems is the result of a number of processes, which either bring the particles together (coagulation) or disrupt existing aggregates (dispersion) (Filella and Buffle, 1993; Buffle and Leppard, 1995a, 1995b). Particle size is an important parameter in the characterization

of colloids. Sequential gravimetric sedimentation has been the classical method for measuring PSDs in soils. However, this technique has proven to be unreliable for particle sizes in the colloidal range (1–1000 nm). The reason for the lack of reliability is the combination of Brownian motion and convection currents, which each exert a significant influence on settling at diameters below ~1 μm in water.

Awareness of the environmental importance of colloids, for example, remediation schemes using engineered nanoparticles, and studies on the ecotoxicology of the products created by the emerging nanotechnology industry have accelerated the development of analytical techniques for nanoscale research (Wilkinson and Lead, 2007). These analytical techniques provide quantification, analyses, and characterization of the size, shape, and distribution of colloids in polydisperse systems within the environment (Handy et al., 2008). Some of the techniques more commonly used in soil science for colloid characterization and determination of PSD are reviewed in the following section. These include centrifugation, particle size analysis using the Coulter principle, field flow fractionation (FFF), atomic force microscopy (AFM), electron microscopy (EM), and acoustic spectroscopy. A recent publication by the International Union of Pure and Applied Chemistry (IUPAC) Wilkinson and Lead (2007) provides more detailed information on the various techniques.

It is important to consider that each particle size measurement technique has different accuracy and precision. In other words, detection limits and detection windows, corresponding to different size ranges, are technique dependent (Table 15.3). Not all

techniques are able to accurately measure the full scale of size ranges for colloids in polydisperse samples. Furthermore, most of the colloidal-sizing techniques do not measure size directly, but rather determine a physicochemical property from which the size is calculated (Lead and Wilkinson, 2007). For example, scanning and transmission electron microscopic techniques determine the physical dimensions of the projected area of the particles (Lebron et al., 1999), light scattering and flow-FFF generally determine the diffusion coefficients (Lead et al., 2000; Hassellov et al., 2007), and sedimentation-FFF (Sd-FFF) and other centrifugation-based techniques measure the buoyant mass (Hassellov et al., 2007). Although particle size can be estimated from projected areas, diffusion coefficients, and buoyant mass, the calculations are based on a number of assumptions, which if not met, will reduce the quality of the results (i.e., sphericity, homogeneous charge distribution, absence of coulombic interactions among particles). Therefore, it is not uncommon to obtain different PSDs for the same sample when using different techniques (Lead and Wilkinson, 2007). Even more direct techniques like scanning electron microscopy (SEM) and environmental scanning electron microscopy (ESEM) have their limitations. Doucet et al. (2004) observed differing colloidal morphologies in preparations obtained from the same sample with SEM and AFM. They attributed these differences to the sample preparation required for each technique. The difficulty in obtaining similar PSDs using different techniques indicates the limitation of the individual techniques. Therefore, it is good practice to use the results of several characterization techniques simultaneously (Lead and Wilkinson, 2007; Hassellov et al., 2008).

15.1.3.1.1 Measurement Methodology

Minimization of sample handling and processing is recommended when analyzing colloidal systems. Currently, no in situ technique allows direct measurement of the PSD for soils. Furthermore, measurement of colloid particles cannot be compared to standard samples to evaluate the quality of measurements made because there are no accepted standards or reference materials for natural colloids (Lead and Wilkinson, 2007).

15.1.3.1.2 Electron Microscopy

EM is one of the few techniques capable of measuring the size of particles across the entire colloidal range (Table 15.3). Both transmission electron microscopy (TEM) and SEM require deposition of aqueous suspensions, sample evacuation, and in the case of SEM, sample coating with a conducting material, typically graphite or gold, to reduce charging from the beam. Hence sample preparation can, and most likely will, alter the original particle morphology and size distribution (Buffle and Leppard, 1995a, 1995b; Chanudet and Filella, 2006). However, new sample preparation techniques are constantly being developed to counteract artifacts generated by dehydration. For example, freeze-drying techniques or the use of hydrophilic resins and multimethod TEM sample generation techniques can be used to stabilize the three-dimensional structure of colloids (Mavrocordatos et al., 2007).

TABLE 15.3 Operational Range of Colloid Particle Size Characterization for a Variety of Analytical Techniques and the Inferred Colloidal Dimension Quantified by Each Technique

Analytical Technique	Quantified Parameter	Approximate Analysis Size Range (nm)
Filtration	Equivalent pore size diameter	100–>1000
Ultrafiltration	Equivalent molar mass	1–100
Centrifugation	Equivalent spherical volume diameter	10–>1000
Dialysis	Equivalent molar mass	0.5–100
ESEM	Projected area	40–>1000
SEM	Projected area	10–>1000
TEM	Projected area	1–>1000
AFM	Three dimensions	0.5–>1000
Fl-FFF	Hydrodynamic diameter	1–1000
Sd-FFF	Equivalent spherical volume diameter	50–1000
DLS	Hydrodynamic diameter	3–>1000
Acoustic spectroscopy	Equivalent particle diameter	5–>1000

ESEM can, in theory, be used to quantify colloids under ambient conditions, as can AFM that is generally used only to determine the dimensions and characteristics of individual colloids. While minimal sample manipulation is an advantage, the disadvantage is a reduction in the resolution of the techniques; both ESEM and AFM produce much better resolution at lower relative humidity. Another serious problem in AFM imaging of liquids is the alteration of the AFM-derived signal due to the uptake of nanoparticles onto the AFM cantilever (Lead et al., 2005). Applications and new sample preparation techniques for environmental colloids using AFM are discussed by Balnois et al. (2007). Force-volume mode AFM has been used to evaluate the heterogeneous distribution of charge on clay surfaces (Taboada-Serrano et al., 2005).

Microscopy, despite being a very powerful technique, is not widely used for routine particle size analysis. The reasons for its limited use are the high cost of the equipment and the small sample volumes that can be scanned at any given magnification. Image analysis software facilitates the quantification of the different particle metrics in the micrographs. However, obtaining sufficient particles to allow representative and robust statistics requires the scanning of many micrographs of the specimen. Nevertheless, the determination of morphology and particle shape factor still remains the strength of microscopic techniques. Automated instrumental analysis routines that take advantage of enhanced beam stability combined with image analysis software, and greater computing capacity have the potential to address such limitations (Seaman, 2000; Laskin and Cowin, 2001). Additionally, SEM, ESEM, and TEM coupled with energy dispersive x-ray (EDX) spectroscopy can provide valuable chemical information about individual particles. It must be recognized that the resulting x-ray signal in SEM may be generated from a sample region larger than the particle of interest (Goldstein et al., 1992; Seaman, 2000). Furthermore, TEM can also, by measuring the x-ray spectra emitted by the specimen, resolve crystal spacing. Selective area electron diffraction can be used to identify colloidal minerals and to determine their degree of colloid crystallinity.

15.1.3.1.3 Centrifugation

A particle falling through an infinite fluid will eventually travel at a terminal constant velocity determined by the size of the particle and the resistance offered by the fluid. The terminal velocity in a centrifugal field is not constant, but rather a function of distance from the axis of rotation. Measurement of this radius is necessary in order to calculate the particle size. The relationship between the movement of the particle and the movement of fluid around that particle may be reduced to the Stokes equation. For fluid moving past a particle of diameter (d_p), the ratio of the inertial transfer is described by the dimensionless parameter, the Reynolds number (R_E):

$$R_E = \frac{\rho_0 u d_p}{\eta} \qquad (15.1)$$

where u is the velocity. If $R_E \leq 0.2$, the fluid conditions are described as streamlined or laminar, and the drag on the particle is due mainly to viscous force within the fluid. Particles with high densities or large particle diameters may be moving with velocities that exceed $R_E = 0.2$, and in this situation, they are likely to enter the region of turbulent flow, where velocities are more difficult to calculate. In a centrifugal field, Stokes' equation has the form:

$$u = \frac{(\rho - \rho_0)\omega^2 d_p^2}{18\eta} = \frac{\ln(r/s_0)}{t} \qquad (15.2)$$

where
- ω is the rotational velocity (rad s^{-1})
- t is the time (s) required for a particle of diameter d_p to move from its starting point radius (s_0) to the analytical radius (r)
